THOSE who hope that the British House of Commons will eventually grow to be an effective critic of Government policy in science and technology will not have been much encouraged by the publication a week ago of the report of the sub-committee of the Estimates Committee on the conduct of space research and development in Britain (see *Nature*, **215**, 685; 1967). With all its brash espousal of popular but thoughtless causes, the report is unlikely to have much influence in the ways in which its authors intended. Indirectly, it will probably reduce the credibility of the Estimates Committee, which is unfortunate at a time when it is clear that a conscious attempt is being made to give the committee a sharper cutting edge on policy, and when other sub-committees of the same body are trying to win support for daring but imaginative proposals for penal reform. In the circumstances, it might be kinder to let the report sink quietly into the wastepaper basket where it belongs, yet many of the questions raised by its appearance and its failure are of lasting interest. To know just why many of the conclusions to which the sub-committee was driven are faulty is in itself important. And how did the committee go so badly adrift? And what kinds of conclusions should it have reached? These questions also deserve an answer.

The first complaint against the committee's handiwork is that it has somehow failed to appreciate the subtleties of the problem with which it has been wrestling since February 1966. In the event it is not surprising that some among the many recommendations in the report should be entirely sensible. If you keep on tossing pennies in the air, some of them are bound to come down in the way which is predicted. Unfortunately, however, the committee's argument is so thin that very little of what it has to say will carry conviction. It is sound enough, of course, to resist the claims of the National Industrial Space Committee that extra rockets on the ELDO pattern should be ordered quickly even though there are no customers for them in prospect, although it cannot have taken particular cleverness for the members of the committee to have recognized this echo of the familiar cry that it is often more important to order equipment than to use it. Politicians should be familiar enough with that by now.

The committee is also right in saying that there should be no further increase in the rate at which the ELDO organization is empowered by money to launch its clever apogee-perigee rockets, but it has inexplicably shrunk from what would have been the useful task of asking whether and in what form ELDO should continue after current programmes have come to an end. The truth is that ELDO in its present form owes too much to the mixed motives which attended its forma-

tion at the beginning of the decade. Although the committee collected plenty of evidence to show that the work of ELDO is badly co-ordinated, and that participants in the programme do not easily acquire a sense of familiarity with those developments not directly in their charge, much of this trouble can be traced to the haste and the muddle in which the organization was set up. At the same time, however, if European countries are ever to produce large launching rockets—and it is not obvious that they should—it will obviously be easiest to do this within the framework of European collaboration. In other words, if ELDO did not exist, it would be necessary to think of inventing it. The committee would have done a public service if it had tried to decide whether reform is feasible.

Instead, the committee has settled for some woolly statements about the need that "within the total space budget the greater share should be spent on the national programme and the lesser share on the international programme". As it happens, in the current financial year, the British contribution to the budget of ELDO will be £9.69 million out of a total of £30.55 million, with the European Space Research Organization (ESRO) and the International Telecommunications Satellite (INTELSAT) taking £600,000. One thing that rankles with the committee is that international obligations are a smaller proportion of what is spent in France, but this is of course beside the point. There can be no simple rule to determine how a balance should be struck between domestic and international expenditure.

These, however, are almost minor transgressions. It is much more serious, and much more important, that the committee seems to have emerged from its long sequence of meetings entirely innocent of a clear view of what space research and development is for. Only this can account for the strange repetition of the cry that there should be what the committee calls "a national space programme with a budget of its own" in the charge of a single minister—the Minister of Technology. The truth is that there are at least three quite different sets of reasons why countries such as the United Kingdom should put money into space research and development, which means that there must be at least three different sets of yardsticks for deciding what to spend. In other words, where the objective is to provide opportunities for people from British universities and laboratories to carry out experiments with rockets or satellites, it is entirely right and proper that decisions about how much to spend should be taken within the framework of the Science Research Council, for only then is it possible to match the benefits of such expenditure against those likely to be obtained by spending money on other

kinds of scientific research. In the same way, it is proper that the Ministry of Defence should take decisions about the usefulness of certain military applications of Earth satellites, chiefly in telecommunications, by matching the potential advantages against the costs of these and alternative developments. Without knowing much more than it troubled to find out about the criteria which are being used in making these comparisons, it is, of course, nonsense for the Estimates Committee to claim that an expenditure of between £30 million and £35 million a year is more or less what Solomon would have settled for.

The committee's sense of muddle extends to what it has to say about the commercial benefits which may eventually stem from space research and development. Prompted by the National Industrial Space Committee, the Estimates Committee sheds a great many tears about the way in which British manufacturers have not won enough contracts from organizations like ESRO to balance out what the British Government contributes to them. Considerations like these, however, have nothing at all to do with the question of how much money should go into the commercial development of devices such as communications satellites, and how governments like the British should seek to organize and to exploit them. If there is a case at all for the development in Europe of means of building, launching and operating communications satellites, it must rest on a hard-headed estimate that the economic benefit to be derived by means like this is measured in hundreds of millions of pounds a year. British companies could obviously do better in winning contracts from ESRO, but carrying out jobs for a research organization can never bring in more than chicken feed. It is foolish of the committee to suggest that there should be what it calls a national space programme in order that the companies can be better equipped to acquire a bigger share of this marginal business. There is rather more sense in what the committee has to say about the need of a tighter relationship between the Ministry of Technology, blessed for better or worse with involvement in ELDO, and the General Post Office, traditionally responsible for negotiations on the operation of the international communications network. It is also sensible of the committee to draw attention to the opportunity that will present itself, in 1970, for a revision of the rules which at present govern the operation of INTELSTAT—the consortium which owns and operates the system of communications satellites launched from the United States. These—with the splendid index—are the few virtues in a bad report.

What has gone wrong? Why has the committee followed so many false scents? Nobody who reads the minutes of evidence can fail to be impressed with the amount of time spent on explanation. Witnesses were more often tutors than defendants, and it is clear that many of the lessons they attempted to impart have failed to sink home. Although it is unreasonable to expect that members of the estimates committee should be knowledgeable about the technicalities of

space research and development, it is entirely proper to ask that they should provide themselves—or be provided—with professional help when they embark on highly technical enquiries. Congress in the United States, which has a long experience of legislative committee work, learned this lesson long ago. Those who would increase the influence of the British Parliament by strengthening the committees will undermine their own efforts if they do not quickly follow suit.

The estimates committee was also exceedingly unwise in its choice of witnesses. It is entirely understandable that the civil servants responsible for the administration of money now spent on space research should have been fully represented, but why should the only outside body represented in the evidence have been the National Industrial Space Committee—a lobby if there ever was one? Certainly the chairmen of the scientific committees to which the British Government looks for advice could have given a much needed account of how policies on space research are determined. The Post Office, which has still to live down its recent brash advocacy of a system of low-level satellites for communications, is not the only authority on whether, and when, independent launchers for communications satellites would be a European asset.

What, then, should be done? Scepticism about the report may at least have the virtue of suggesting the kinds of studies which need to be carried out if countries such as the United Kingdom are to form rational policies. Clearly there is a need for a more deliberate appraisal of the potential value of ESRO as a means of sustaining scientific research. It would also be splendid if Europe as a whole could decide what needs to be done about communications satellites.

Where ESRO is concerned, the example of CERN is instructive. Both institutions have been established so as to provide facilities for research which are beyond the resources of any single member. Both of them, to some extent at least, involve expensive capital installations. It is true that CERN has from the beginning had the advantage of a much more easily recognizable centre for its operations—the accelerator at Geneva—but this does not entirely explain why ESRO has won many fewer friends. A part of the trouble seems to have been a somewhat muddled organization, which is why there are now hopes that Professor Bondi will be able to do much to invigorate the organization when he arrives there in the autumn. It is also true, however, that some of the uncertainty which surrounds ELDO has afflicted ESRO. It is even suggested that the two organizations should be merged, which makes very little sense unless on the principle that if all your eggs are rotten, they may as well be in the same basket. The ideal would be to keep ESRO going as an independent unit and to see whether it can become a vehicle for executing a substantial part of the research in this field which European scientists wish to undertake and their governments are prepared to underwrite. It is entirely possible that the constitution of ESRO might be modified in

such a way as to make the organization a more effective focus for space research in Europe. One of the strengths of CERN is that countries which have paid their subscriptions are tempted to get the best value for their investment by carrying out as much work as possible at the central establishment (which has not, of course, brought strictly national activity in high energy physics to a halt). If there were an incentive like this for ESRO, that organization would be enormously strengthened.

It is also important that there should now be a cool appraisal of the commercial benefits of building large launching rockets in Europe. As things are, the ELDO launcher casts a long shadow over everything. People are naturally reluctant to acknowledge that the usefulness of this machine is limited after so much money has been spent on it. The result is that plans for satellite development in ESRO, and plans for launching communications satellites in Europe, are being made to hang on this one rocket. Even at this late stage, however, it is entirely possible that it would be better to start again from scratch on the development of another rocket. That is something which ought to be considered. It is also possible that a suitable organization in Europe could make a sensible (and lasting) agreement with the United States on the use of even bigger rockets. Certainly this is a possibility which ought to be explored. Much will depend on the form of the revised INTELSTAT agreement, which is certain by the seventies to seem on both sides of the Atlantic to be too much dominated by the United States. But in this sense, some hard work now on the diplomacy of international communications could help enormously to simplify the problem of deciding what kinds of rockets, if any, should be developed and built independently in Europe. To begin with, however, it is essential that these discussions should be undertaken on a European basis. The common interest of the non-rocket countries is too powerful for any other course to be acceptable.

## HOW BIG IS CHINA?

How soon will China be a nuclear power to be reckoned with? The prophecies which the Joint Committee on Atomic Energy has been making about the development of nuclear weapons and missiles in mainland China (see page 805) are sobering but not much of a surprise. For a decade now, Chinese statesmen have made no secret of their intention to develop a strategic striking force. Indeed, on several occasions since the official opening in 1958 by Mr Khrushchev of the Russian research reactor in Peking, commentators elsewhere have been inveigled into the assumption that Chinese ambitions had already been translated into fact. Although it is now clear that preparations for the manufacture of nuclear explosives were well under way even before 1958, the course of events since then has not in any way been unexpected. The interval

of time between the first fission explosion and the first fusion explosion in China may have been shorter than elsewhere, but that is a simple consequence of what must have been an explicit decision in China that the only weapons worth having are thermonuclear weapons. Certainly the obvious difference between the speed of development in China and in France seems to stem directly from Chinese confrontation on the building of diffusion plants for the manufacture of fissile uranium. The joint committee is understandably puzzled that the French are making what seems to be heavy weather of the production of a thermonuclear weapon, but it is probably prudent—even fair—to remember that the origin of the French decision to manufacture nuclear weapons was clouded, to say the best of it. To begin with, the French government talked chiefly of tactical uses for nuclear weapons. Given Chinese single-mindedness, it is not surprising that China has forged ahead with the manufacture of nuclear explosives of all kinds.

The development and manufacture of missiles are another matter. The joint committee seems to have convinced itself that the Chinese are already possessed of medium range ballistic missiles and that rockets able to travel greater distances will be in service in the early seventies. No doubt the committee has access to unpublished information about developments in China, and there is no question that the news it has to give of the development of delivery systems for nuclear weapons is potentially important. Because the Chinese aircraft industry is as yet comparatively unsophisticated, it has always been evident that China could not become an effective nuclear power without some machinery for the delivery of nuclear explosives. It would be entirely consistent with the policy of seeking to become a nuclear power as soon as possible if the Chinese had decided not to bother with the development of aircraft but to go straight for long range missiles. Nevertheless, it would be surprising if China were able by the early seventies not merely to design and prove a long range missile, but to manufacture it in large numbers and then integrate it into a strategic striking force. Experience elsewhere shows that there is often a lag of several years between the first appearance of a new sophisticated weapon and its effective deployment in the field. This is why it is probably safe to think that it will be nearer the middle of the next decade than the beginning when the Chinese are able to level a credible threat against other strategic nuclear powers, to the west or to the east of China. This no doubt is why Mr Robert McNamara in the United States has been able to insist that an anti-ballistic missile system will not be strictly necessary before the mid-seventies.

A lot can happen before then. One possibility is, of course, that domestic troubles in China may prevent the Chinese government from maintaining a coherent and consistent defence policy but it would be rash for people outside China to rely on that. It is, however, more than likely that long before the Chinese government would wish directly to pose a missile threat

against—say—the United States, it will find itself preoccupied with more immediate and more local problems. In particular, the Chinese government is likely to find itself increasingly made militarily impotent in the immediate neighbourhood of mainland China by the lack of advanced conventional weapons. For one thing, this deficiency is likely to limit the extent to which the Chinese are able to think of using their new nuclear explosives even in the affairs of south-east Asia.

In other words, one of the immediate and somewhat paradoxical consequences of the speed with which nuclear explosives have been developed in China may well turn out to be a recognition that single-mindedness has created a lopsided military apparatus. Obviously it would be folly to hope that the Chinese will noticeably slacken their efforts on nuclear weapons for the sake of a more balanced programme, but the next few years are likely to bring some sharp reminders that the mere possession of nuclear weapons does not make up for a lack of conventional strength. China, like the other nations which have developed nuclear weapons for themselves, will soon begin to learn that nuclear explosives do not bring instant prowess.

What will happen after that? If it is reasonable to assume that Chinese nuclear weapons will be substantial by the middle seventies, it is natural to expect that the existing nuclear powers will be forced in some way to respond. The development and deployment of anti-ballistic missiles in the United States is one obvious possibility, although it is not immediately obvious why the kind of strategic balance which has developed between the Soviet Union and the United States should not also help to nullify the Chinese threat. Is it so entirely outrageous to look for some kind of dialogue between China and the other members of the nuclear club? In practice it is hard to think that the isolation of China from the rest of the world can persist unchanged for yet another decade. In the long run, and possibly in the immediate future as well, it may be more profitable for the rest of the world to respond to what is happening in China by talk rather than by the development of nullifying hardware.

## MOLECULAR MODELS

A REALIZATION of the importance of molecular model building was a major factor in Pauling's determination of the  $\alpha$ -helix of proteins and Watson and Crick's discovery of the structure of DNA. But model building—apart from providing a way of refining molecular structures which are being determined by X-ray crystallography and giving tangible representations of the final molecular structure—can by itself, in the right hands, provide a method for predicting the probable atomic structures of macromolecules which, for one reason or another, cannot be directly determined by X-ray diffraction. Such predictive model building is, however, fraught with pitfalls and only when it is

treated as a strict discipline can any reliance be placed on the results it yields. Of necessity, assumptions must replace data, and the validity of a model structure entirely depends on the validity of the principal assumptions; but a model must in addition bring together every scrap of relevant chemical and stereochemical data that is available, no matter how obtained, and synthesize it into a coherent whole.

The elucidation of a unique structure of a small but very interesting part of the transfer-RNA molecule, the anticodon loop, by Fuller and Hodgkin, which is reported on page 817, is a case in point. Crystallographic analyses of *t*RNA are impossible simply because, despite numerous efforts and some red herrings, it has so far proved impossible to crystallize the material. However, since Holley and his collaborators determined the nucleotide sequence of alanyl *t*RNA, the sequences of three other species of *t*RNA have revealed certain features common to the four molecules. Moreover, the structure of double helical RNA, that of reovirus, has been determined by X-ray diffraction, and the importance of the phenomena of base stacking in non-helical regions of nucleic acid molecules has been recognized. Fuller and Hodgkin have used these data and the accumulated information on bond lengths and angles in ribonucleotides and nucleotides to construct their model of the anticodon loop. By restricting their effort to this small region of the *t*RNA molecule, Fuller and Hodgkin have provided themselves with fixed points—the two free ends of the loop and a region of base-pairing. When the seven unpaired nucleotides that form the anticodon loop are arranged to maximize base stacking, taking into account all the known stereochemical constraints, there appears to be a unique structural solution for the four species of *t*RNA: five bases are stacked and two are in a less ordered configuration.

The model engenders confidence because of its stereochemical neatness and because it is based on two eminently reasonable assumptions—that there should be maximum base pairing and maximum base stacking. Moreover, any model must of course be reconcilable with the known biological functions of a molecule and the proposed structure of the anticodon loop is. It accommodates the genetic data on which Crick based his wobble hypothesis and it allows two *t*RNA molecules simultaneously to recognize adjacent codons of a messenger RNA molecule.

Obviously the structure of a molecule can never be proved by model building alone. Sometimes it may only show what structures are impossible, but may leave several alternative probabilities. When, however, a model accounts uniquely for all the known structural and functional properties of a molecule, it is probably substantially correct. It remains to be seen whether or not the model now proposed will stand when the nucleotide sequences of more species of *t*RNA have been determined. Meanwhile, model building may well be used to find the probable structure of another vital part of the *t*RNA molecule—the amino-acid recognition site.

## NEWS AND VIEWS

### Unfinished Business

THE disappearance of the British Parliament on vacation has left several important issues in abeyance. By the time the political season begins again, and certainly by the time that Parliament reassembles in October, a great many tasks will need urgently to be attended to. In science and technology, perhaps the most glaring need is for a decision on the future of the Atomic Energy Authority; although it seems to be unlikely that a radical change in the structure of the authority will be made in the months immediately ahead, the fact that a successor to Lord Penney (who moves to Imperial College in October) has not yet been appointed is one sign that there are decisions to be made. (The annual report of the authority, which usually appears in the summer, is being held up until the autumn, but this is probably more a sign that Lord Penney wishes to make its appearance his final public comment on the authority's business than a symptom of uncertainty.)

The report of the Advisory Council on Scientific Policy, expected about May this year, is also late, although it is known that the final draft has now gone to the Secretary of State for Education and Science. In the weeks and months immediately ahead, the council is likely to be preoccupied with the fixing within the government of targets for spending by the research councils into the early seventies. A year ago it seems to have been agreed that government expenditure on civil science should continue to increase, but at a declining pace. In particular, it has been laid down that in three consecutive years increases should amount to 10, 9 and 8 per cent respectively. Having established the point that plans for spending on research should be settled in broad outline three years in advance, the advisory council is now faced with the need to combat the Treasury's instinct to continue the progression 10, 9, 8 in such a way as to entail a continuing reduction in the pace of growth. The appearance of the council's report on the cost of what is called "sophistication", also due soon, is expected to make an important contribution to this question.

Another matter that will be looked at closely in the autumn is the operation of the Science Research Council, then to be blessed with a new chairman in the person of Professor Brian Flowers. The Science Research Council is, of course, the largest of the four research councils concerned with the natural sciences.

### Women not Wanted

FOR a nation suffering from a shortage of doctors, Britain seems to be remarkably prodigal of willing helpers. Last week a twenty-two year old girl left Britain to take up a place in a medical school in Prague, after she had failed even to be interviewed for a place at a British school. The girl, Miss Diana Pearce, who had three A levels and ten O levels, had been applying to London and provincial hospitals for

the past four years. She will now, presumably, be learning Czech in order to qualify as a doctor. Miss Pearce is unusual only in her determination; at various London hospitals last year the number of women applicants for each place varied between twenty and forty. Only about twenty per cent of the places at medical schools are for women, and competition for them is significantly higher than for men.

When Miss Pearce returns from Czechoslovakia, fully qualified, she will still not be able to practise in Britain. This is a predicament she will share with doctors holding qualifications from every country outside the Commonwealth, South Africa, Eire and Burma. If she only intends to remain in Britain for a short time, she may be registered temporarily with the General Medical Council. If, however, she decided to stay, she would have to acquire one of a number of British qualifications, a process that could possibly take as much as two or three years.

At the same time, two foreign doctors working in Britain have had their temporary registrations cancelled. One of these, a Polish woman doctor, had married an Englishman, and by signifying her intention to remain in Britain had disqualified herself from temporary registration. The other, whose case is still under review by the General Medical Council, and whose name has not been revealed, apparently had his registration cancelled while he was in process of taking examinations for British qualifications. He had already passed one examination. If the Council refuses to rescind its decision he has said that he will go abroad.

The reason why, under Act of Parliament, the General Medical Council will not allow licentiates of foreign medical colleges, including those of the United States and Europe, to practise in Britain without these preliminaries is that reciprocal agreements have not been made with its counterparts in these countries. Before the Second World War agreements did exist with Belgium, Italy and Japan, but these lapsed during the war.

### Cheap Digs for Students

THE University of Lancaster is going ahead with a scheme for cheap student accommodation that may prove a model for universities in the future. In its new building, to be completed in 1969, there will be no large communal rooms, but only self-contained flatlets. Each of these will house ten or eleven students, in single or double rooms. While the flats will have dining-room kitchens, students will be able to eat in their colleges, with which the new building will be integrated. Because of the lack of expensive communal facilities in the new building, and because it will stand in the university's own grounds, the cost will be only £700 per student, compared with £1,200 at other institutions. This in turn will mean low rents—three pounds for a single room, ten shillings less for a double room. Even so, the university hopes to make a profit, and so has been able to finance the scheme through an insurance company, instead of the University Grants Committee. £500,000 will be borrowed, and repaid over thirty years at an annual rate of £43,000. The cost of heating, light and maintenance will bring this sum to £66,500, while the revenue from 605 students will be £68,500, if all goes according to plan.

Conventional university discipline, communal meals, and times for visitors, will be impracticable in the new building. And it will be interesting to see how students take to living together in such large groups. The social and financial implications of the scheme will be discussed by a sub-committee of the Committee of Vice-Chancellors, in order that other universities may be informed of Lancaster's experiment.

## Post Office Computers

AFTER the haste with which the Post Office (Data Processing Service) Bill went through Parliament, the service seems to be taking some time to get down to work. The service is being planned by the General Post Office Computer Development Department, whose director is Mr C. R. Smith. Although computer time will be offered for sale almost immediately, the data processing service is not expected to become fully operational for about two years.

At present the Post Office has computer centres in London, Derby, Portsmouth, Edinburgh and Lytham St Annes, with computer equipment worth £4 million already installed and working. It plans to set up further centres at Bootle, Leeds, Glasgow, Bristol and Manchester. The cost of setting up this service is expected to be about £12 million. By 1971 the Post Office hopes to have twenty large computers in operation up and down the country, all linked together.

The computers will be primarily for the use of the Post Office—the Bootle centre, for example, will work with the Giro banking system, but as part of the service the Post Office will sell off surplus time. Twelve of the GPO computers are English Electric-Elliott and one is made by ICT. There are further English Electric-Elliott computers on order.

## Computers for Columbia

A SCHEME for permitting access to the computers being used at Columbia University from the offices of individuals making use of them is to be carried out by 1969. Altogether, the university is planning to spend \$3 million on the provision of 200 access points scattered around the Columbia campuses. The intention is to allow individual researchers to communicate directly with the whole of the computer system at Columbia. It has been calculated by those responsible for the development of the new system that the provision of several access points will increase five-fold the present power of the computers already installed at Columbia.

Apparently the planners are thinking simply of the extension of the present uses of the computer centre at Columbia, which has in the past four years grown so that it handles an average of between 6 and 7 million jobs each day. One advantage of providing multiple access to the computing network is that it will be easier for demands for small blocks of computer time to be met. In practice, it appears that the computer centre at Columbia tends to accumulate throughout each week a backlog of work which is cleared at the weekend. The network of access points now being provided is intended simply to help with the management of the computers' time. The system differs, of course, from true multiple access systems in which several jobs are processed more or less simultaneously.

## Air Fares Go Up

FROM September, air fares in Britain are to rise between 11 and 15 per cent. The Air Transport Licensing Board last approved an increase of fares in April 1966 so that this second fare rise within eighteen months has caused a certain amount of comment.

Comparisons are often made between the costs of travelling between London and Glasgow, and between San Francisco and Los Angeles: the British trip costs 7.49 cents per mile, the American only 3.96 cents. But San Francisco and Los Angeles are two poles of population density in a way in which London and Glasgow are not. A better comparison could be made with the New York-Pittsburgh route, on which passengers are travelling between a huge metropolis and one of a number of large industrial cities in a densely populated region. The cost of this journey, of length similar to the other two, is 6.87 cents per mile; and it is interesting to note that the sector is served by two carriers, one of which, Allegheny Airlines, is subsidized by the Federal Government. Pilot salaries are, of course, higher in the United States, but airport charges are heavy in Britain—the first thirty passengers on a Vanguard flight between Manchester and London pay for the airport charges, according to BEA. Air fares in Europe are often more expensive than in Britain, so that the new increases may well have been unavoidable.

Yet even if fares are relatively low, it is impossible to say how far the size of the increase is justified. This is because, although the Licensing Board has access to the accounts of the various airlines, it is not permitted to make them public. Private individuals have no right to object to the raising of fares, but the board sometimes allows them to make statements, especially if they represent groups of people likely to be affected by changes in fares. These individuals are then allowed to "cross-examine" the airlines; the airlines do not, however, have to reply.

Clearly the Licensing Board is unhappy with the situation. In its report on its decision to raise fares, the board says: "It is unfortunate that the powers under which it (the information on which the decision rests) was obtained do not allow us to make this information public. . . . We think that a general disclosure of such information would be beneficial to British aviation".

## More Scientists as Astronauts

AMONG the new NASA intake of 11 scientist-astronauts there is a Welsh chemist and an Australian physicist. The inclusion of these two naturalized American citizens breaks new ground for the American programme—indeed the Australian, Dr Philip Chapman, only gained his US citizenship this May though he has been working at the Experimental Astronomy Laboratory of MIT since 1961. The Welshness of Dr John Llewellyn—despite 9 years' work in North America—is not to be concealed; besides his own good Welsh name his wife was born Valerie Davies-Jones and his 3 children rejoice in the names Gareth, Sian and Ceri Elum-med. Both naturalized astronauts have gravitated to their present appointments by way of Canada. The acceptance by NASA of naturalized citizens for their sensitive manned space programme reflects the new emphasis on appropriate scientific background for the second generation of manned space operations

(post-Apollo). This group is clearly intended for the manning of the Apollo Applications Programme where the premium is put on manned supervision of astronomy from orbit. Four of the 11 have research experience in astrophysics.

As a group, the 16 scientist-astronauts now under active training are less stereotyped than the previous 49 jet pilot recruits. They do not average 2.3 children each as before, and their age spread is much wider—the geophysicist of the new group is only 25 and one of the astronomers is already 40. Dr Garriott, an ionospheric physicist selected in 1965 as one of the first group of scientific astronauts, was in London recently attending the IQSY-COSPAR meeting and renewing acquaintance with the Radio and Space Research Station, Slough, where he had worked for a year before becoming an astronaut candidate. He made it clear that scientists selected were not led to believe that their expertise had been earmarked in advance for a particular mission—quite the contrary. Training, which is a continuous process up to the moment of lift-off, is aimed at broadening scientific experience as well as technical skills—such as piloting jet aircraft. In fact Dr Garriott had come to England from a geological field party in Iceland where some of the volcanic regions are thought to resemble lunar terrains more closely than most terrestrial landscapes.

Of the total tally of 66 astronauts, 56 are on the active list today. An Air Force doctor in the 1965 intake of scientist-astronauts resigned; one of last year's pilot officer recruits was killed in a motor accident in June; three of the regular astronaut groups II and III were killed in aircraft crashes during training; three, including space-walker White, died in this year's tragic Apollo ground-test accident. US Navy Commander Scott Carpenter has just returned to the Navy to pursue his work in "inner space" in the "Man-in-the-Sea" experimental programme, and John Glenn has been seconded to other duties.

## Doctorate Production

THE National Science Foundation of the United States has issued its estimates of scientific manpower for the next decade. On the assumption that the student population will continue to increase at its present rate, the United States will need three hundred and seventy thousand science lecturers and research workers in universities by 1970. It is expected that the percentage of those university workers with PhD degrees will fall over the next few years, but will return to the present level in the mid seventies. The estimates of those taking the bachelors' and doctors' degrees are as follows:

	Bachelors	Doctors
1965	238,000	12,100
1970	348,000	20,000
1975	428,000	30,500

Of the newly qualified PhDs of recent years, about 15 per cent were foreign, and the estimates assume that there will be no change in this proportion.

Though the United States will be doubling what the foundation calls its "baccalaureate and doctorate production" in the ten year period, its population is only expected to increase by 18 per cent, to two hundred and thirty million. Alternatively, the progression of the United States towards a nation in mortar boards can be shown by calculating the proportion of babies

born in any year who are destined to become science graduates at the age of twenty-one. Of those born in 1944, one in twelve received a B.Sc. in 1965. Of those born ten years later, one in nine are expected to graduate in science, and more than one in twenty-nine will acquire a higher degree.

The report gives no indication of how far into the future we may expect the expansion of American education to continue. There are more ways to produce doctorates than by training first class minds; the report says nothing of the maintenance of standards. And if baccalaureate production is to double every decade, as it has done, while population output lags behind, can quality control be stringent?

## Missiles for Mao

THE Joint Committee on Atomic Energy of the United States Congress now believes that China will have inter-continental ballistic missiles with nuclear warheads in the early 1970s. Its report states that there is evidence that the sixth and latest Chinese test device was dropped from an aircraft. The fall-out from the fifth test, details of which were not released by the American Atomic Energy Commission at the time, indicated that uranium-238 was being used as fissionable material, and that the fusion material, tritium, was produced by fission-induced decay from lithium-6. The Chinese therefore seemed to have solved most of the problems of designing fusion bombs by last December, and the committee believes that the yield of the fifth bomb may have been deliberately limited, to keep the fall-out over China to a low level. The explosion of a megaton bomb was fully expected. The first four tests conducted in China took place in October 1964, May 1965, and May and October 1966. The third of these was the largest, the size of the weapon being between two hundred and a thousand kilotons. There is evidence that lithium-6 was involved in this third bomb, as well as the fifth. The other three were smaller, the first being twenty kilotons, while the other two were slightly larger, in the low intermediate range of between twenty and two hundred kilotons.

Reviewing the French atomic programme in the same report—a strange juxtaposition, since the report is supposed to deal with the effect on United States security of the Chinese weapons—the Committee concluded that France is a long way behind China. It even doubts whether the French will explode a hydrogen bomb in 1968. On the other hand, the French do have a strategic force of Mirage IVs; the Chinese are not known to have a means of delivering their more powerful weapons. China has already developed an intermediate range missile, according to the report, but there are no signs that this is in service. The Chinese are also supposed to be "interested in the development of submarines" armed with long range rockets, though the committee has no knowledge of actual developments.

The report will, no doubt, influence the argument about the development of anti-missile defences in the United States. The committee mentions that the United States will lack defences against a Chinese attack, but does not reveal its views on the establishment of an anti-missile system. Nor is there any discussion in the report of the possible effects of the cultural revolution on Chinese activities. It is difficult

to believe that scientists can long remain undisturbed, or that the Chinese economy can continue to bear the huge burden of the nuclear programme.

## No Diagnosis, No Cure

DURING its twenty year life, the British National Health Service has often been criticized. Usually criticism has been directed at the service, rather than the doctors and nurses who make it up. Recently this unwritten rule has been broken by a book, *Sans Everything*, compiled by an organization called AEGIS (Aid for the Elderly in Government Institutions) and written by Mrs Barbara Robb, chairman of the organization. The book alleges bad nursing practices, mismanagement and even physical ill-treatment of elderly patients in some geriatric and psychiatric hospitals. The book does not name the hospitals, nor its sources of information, explaining that this is done to protect the informers from becoming scapegoats.

After some weeks of negotiation, Mr Kenneth Robinson, the Minister of Health, has persuaded Mrs Robb to tell him confidentially the names of the hospitals involved. This, he said, would enable the truth to be established. But he has now set in motion enquiries which seem calculated to reassure only those who never believed the allegations in the first place.

First, the enquiries are to be held by the hospital boards. In effect the boards are being asked to set up enquiries into their own management of their own hospitals. True, the ill-effects of this will be mitigated by the fact that the committees of enquiry (each with a Queen's Counsel as chairman) will be selected from people from outside the region, but the hospital boards will be responsible for selecting them. (The Lord Chancellor has put forward a list of names of QCs to the minister, who has forwarded them to the boards for selection. Other members of the committees will be a doctor, a nurse, and a member of the public, man or woman.)

Second, proceedings will be held in private, which is never the best way of convincing critics outside. Staff and patients, the ministry says, will be able to give evidence about hospitals in complete confidence. But if they want to make allegations against named individuals, the ministry adds, they must be prepared to do so in the presence of the individuals accused. It is hard to think that nurses, who are best placed to know what is going on, will come forward to give evidence against matrons.

## Merger for Engineers?

THE Institution of Mechanical Engineers and the Institution of Heating and Ventilating Engineers are considering the possibility of a merger. The stimulus for the talks seems to have been the desire of the IHVE to join the Council of Engineering Institutions—for this a Royal Charter is necessary. The IHVE has twice applied for a Royal Charter, a form of official recognition which entitles the institution to represent its members, award qualifications and give evidence or comment on legislation to government departments or working parties.

When the IHVE first applied for a charter, in 1948, its request was turned down. In 1962 it applied again, but the decision was held in abeyance. The institution

also applied to join the CEI, and during discussions it was suggested that the position might be easier if the IHVE were to consider the possibility of a merger with the mechanical engineers, already members of the CEI. This is the possibility which is now being considered, although both institutions point out that the discussions are still at an early stage.

## Astronomy by Computer

THE Institute of Theoretical Astronomy at Cambridge is now in business. Armed with the tools of their trade—paper, sharp pencils, and an IBM 360/44—the astronomers will have been at work for several months by the time the institute is officially opened at the end of the year.

The institute, of which Professor Fred Hoyle is the director, has been made possible by a grant of £250,000 from the Nuffield Foundation to cover staff costs, and a matching grant from the SRC to buy the computer. The Wolfson Foundation gave a grant to pay for the special building, and the University of Cambridge is also contributing towards running costs. The common factor behind these generous gestures of support seems to have been the fear that Professor Hoyle would turn his thinly veiled hints of emigration into reality. That, at least, seems to have been averted, but Professor Hoyle will continue to be something of a trans-Atlantic commuter. One of the features of the institute will be the provision of facilities for visiting workers, many of them no doubt from America, and joint studies in collaboration with the California Institute of Technology are proposed.

When complete, the institute will have a staff of about 20, all of them post-doctoral. No teaching in the conventional sense will be expected of them, and the institute is not part of any of the Cambridge faculties. There will, however, be some lectures suitable for graduate students. The research work will cover subjects such as stellar structure, relativity, cosmology and celestial mechanics. The joint studies with Caltech, which will give the Cambridge workers access to the outstanding facilities for observational work in California, will include work on the synthesis of elements in stars.

## Immunochemistry Moves to Oxford

A new Medical Research Council Unit for research into immunochemistry is to be set up at the University of Oxford, under the directorship of Professor R. R. Porter, FRS, who succeeds Sir Hans Krebs, FRS, as Whitley Professor of Biochemistry in the university in the coming academic year. The unit will be concerned with investigating the structure of antibodies, and its relation with their function. The problem is to discover how antibodies can combine specifically with an unlimited number of different antigens. It is hoped that research into this will throw light on the formation of antibodies, and allow a greater control of immune reactions. Some reactions, such as tissue graft rejection, are, however, caused by cells, not antibodies, and the unit will begin studies of the relationship of the two types of reaction.

Professor Porter, who has been Professor of Immunology at St Mary's Hospital Medical School since 1960, established the MRC Research Unit in Immuno-

chemistry there two years ago. In 1966 he was given the Gairdner Award of Merit for his work in this field.

## More Defenders for Aldabra

THE US National Academy of Sciences has allied itself with the Royal Society in the society's war with the British Ministry of Defence over the proposed airfield on the island of Aldabra in the Indian Ocean. The Academy has been having informal conversations with Federal agencies in the hope that another site might be found.

The Royal Society also announced this week details of an expedition to the island to gather as much information as possible before any development might start. The expedition will consist of three phases: a short-term dry season phase, during this month and next, to complete reconnaissance observations started in 1964, to investigate the lagoon area, to study land molluscs, and to begin long term studies on the giant tortoises, birds and marine life; a long term dry season phase from September to December, to continue the studies on tortoises, birds and marine life; and a wet season phase, from December to March 1968, to continue this study and begin studies on insects and land plants. The overall leader of the expedition is Dr David R. Stoddart, a lecturer in the Geography Department at the University of Cambridge. He helped carry out the reconnaissance observations in 1964.

A decision is expected from the Ministry of Defence on the future of Aldabra by May 1968, but scientists may be able to take heart from the fact that in some circles the strategic value of a base on the island is in doubt. Mr Alastair Buchan, director of the Institute for Strategic Studies, in a letter to *The Times*, said that he had great difficulty in understanding what function a base tucked away in that corner of the Indian Ocean would serve, unless it was for British or American military intervention in Southern and East Africa—a role that had dubious credibility. He suggests that Gan, Diego Garcia and the Cocos Islands provide natural staging bases for south-east Asia unless the ministry is contemplating the bizarre alternative of trooping from Britain to Asia via Ascension and Aldabra, which are 4,500 miles apart, the extreme load range of the most powerful aircraft under development.

## Where to put Reactors

THERE is every prospect that the US Atomic Energy Commission will persist with its cautious policy on the siting of reactors and that it will in the process win the approval of most interested parties. So much can be inferred from the report of the hearings on the licensing and regulation of nuclear reactors held in April and May this year by the Joint Committee on Atomic Energy, the report of which has now appeared. The AEC itself, in the person of the chairman, Dr Glen Seaborg, takes the line that more experience of the operation of reactors with the capacity of those now being installed at electricity generating stations will be necessary before it will be possible to lay down criteria for deciding when reactors can be placed, as many of the utility companies would wish, in or near urban areas. In his statement to the joint committee, Dr Seaborg pointed out that although there were in

April 323 nuclear reactors of all types operating in the United States, and although these have accumulated 1,870 reactor-years of operating time, there were only 14 power reactors licensed for civilian operation with an accumulated operating time of 60 reactor-years.

The incentives which tempt utility companies to site reactors close to cities are easy enough to identify, of course. It also seems that in its operation of the licensing procedures, the AEC has been prepared to relax a little the stringency of its rules for deciding how close to centres of urban population reactors can be sited. In granting permission for the operation of a reactor, the AEC specifies a region called an exclusion zone around the reactor which must be entirely within the control of the reactor operator, and then a more extensive area in which the population must be low. The sizes of both areas are determined by the size of the reactor and by some of its design characteristics. In the consent for the building of the San Onofre plant in California, the AEC reduced the exclusion distance from 0.8 miles to 0.5 miles, while the radius of the low population zone was reduced from 12.5 miles to 4 miles. In some respects this site is exceptional, chiefly because it is surrounded by a military reservation, but it appears that similar relaxations of the strictest rules have since been applied to power reactors being constructed in New England.

## Making Medicine Scientific

A FRESH look at the scientific and technical services in British hospitals is to be taken by a committee set up jointly by the Minister of Health and the Secretary of State for Scotland. As the ministry points out, there has been a rapid increase in the use of science and technology in medicine, but so far the expansion has been disjointed and has not followed a coherent policy. The committee will be considering the future organization of the scientific and technical services, and the broad pattern of staffing required. It will be making recommendations to the ministers.

The scope of the survey will be wide. It is to cover the use of physicists, biochemists and physiologists, with their supporting technicians, which will presumably include all the laboratories within the health service. It is also likely to include the newer services such as the cervical cancer smear tests. Since the intention here is to make smear tests available to all women at risk, large laboratory facilities are likely to be needed. The problems of staffing renal dialysis units—the reason given by the ministry several months ago for the slow expansion of the units—might also be worth considering. There are also enormous possibilities of mechanization in intensive care units, with the possibility of continuously monitoring the patient's condition automatically. So far the health service has done little in this direction.

The new committee is to be chaired by Sir Solly Zuckerman, Chief Scientific Adviser at the Cabinet Office and chairman of the Advisory Council on Science and Technology. The other members will be Professor A. R. Currie of the University of Aberdeen, Dr R. Gaddie from the General Hospital at Birmingham, Professor J. E. Roberts from the Middlesex Hospital and the University of London, Mr. A. B. Scott from the United Manchester Hospitals Board of Governors, Professor J. P. Shillingford from the Hammersmith Hospital,

and Dr S. Shone from Sheffield Regional Hospital Board.

## Rabbits by Radio

SOME Australian rabbits are being fitted with miniature radio transmitters to reveal their movements. This and other wildlife research—aimed at the control or conservation of a variety of mammals and birds—is described in the latest annual report of the CSIRO Division of Wildlife Research. A recurrent problem in the control of rabbits is re-infestation, and the animal's movements are being studied to find out how far they can travel. Detailed recording of movements at night—previously difficult in large enclosures or field conditions—will be much easier now that transmitters small enough, and an effective means of harnessing them to the rabbit, have been developed. Transmitted signals are picked up by receivers with directional aerials.

The division's largest single research programme—on the biology of rabbits—also includes investigations into the activity and use of the odoriferous glands which have shown that the sub-mandibular and anal glands are primarily used for territorial marking, while the inguinal gland is associated with sexual attraction. While a rabbit is engaged in social activities, such as examining an object which carries the scent of another rabbit, it drops pellets with the strong odour of the anal gland. This odour is much fainter, or absent, when the rabbit is engaged in non-social activities. This knowledge may help to explain the significance of the "dung-hills" which are found in rabbit territories.

As part of a long term study of fluctuations in numbers of nematode parasites in rabbits in Queensland and New South Wales the CSIRO are looking for the reason for a striking increase in nematodes in females during the breeding season, while at the same time there is a decrease in the parasites in males. Experimental results suggest that the state of susceptibility of a rabbit—particularly a female—to the nematode *Trichostrongylus retortaeformis* is closely associated with its hormonal status. Luteinizing hormones given to does at eighteen day intervals to cause ovulation decreased their susceptibility to the nematodes, while cortisone increased the susceptibility of bucks. The CSIRO feel that this work could lead to the use of hormones in controlling parasites in domestic stock.

## Dissemination of Tumours

from a Correspondent

THE greatest problem in the treatment of cancer is the ability of cancers to invade surrounding tissues and form metastases. Despite this, little attention has so far been paid to the development of screening tests which will detect compounds which affect tumour dissemination or the growth of newly formed metastases. The Committee on Experimental Chemotherapy of the International Union against Cancer recently organized a one day meeting to discuss the possibility of designing such tests.

The meeting opened with a description of the mechanism of cell adhesion and how the altered surface charge of tumour cells decreases their adhesiveness by affecting the properties of the cellular membrane. The importance of this loss of adhesiveness in the shedding of

individual cells from a tumour was discussed. This first stage of tumour dissemination from the point of view of a physical chemist was then supplemented by accounts from biologists of the various steps in the formation of secondary deposits. Tumours penetrate surrounding tissues by invasion or infiltration or may be intravasated by mechanical pressure. Then follows dissemination through the circulation followed by lodgement and growth. The ability of various organs to trap disseminated tumour cells varies greatly. Intracerebral inoculation of tumour cells to rats or mice is followed by the appearance of these cells in the lung and liver and only later in the kidney. The presence of malignant cells trapped by tissues can be demonstrated by a number of techniques including tissue bioassay, isolated organ perfusion and plating techniques. But even if an organ is efficient in trapping disseminated tumour cells, this is no indication that a secondary tumour will eventually appear. Injection of rodent tumour cells into chick embryos has shown that particular tumours are trapped most efficiently by liver, spleen and kidney, with brain the least efficient organ, but it is only in the brain that tumours appeared. The site of tumour growth in the chick embryo depends on whether or not the injected tumour cells have lost their strain specificity or on the degree of malignancy of the tumour. Time did not allow the presentation of the majority of papers on the factors affecting cancer dissemination and metastases, although evidence was presented that known chemotherapeutic agents could influence the behaviour of tumours, probably by affecting immunological mechanisms.

The actual test systems available for studying the effect of compounds in inhibiting cancer dissemination or the growth of metastases are few. Three dimensional growth of tumours or embryonic tissue in a matrix consisting of cellulose sponge coated with collagen enables the study of tissue architecture and of the interaction between tumours and embryonic tissue. Such a system would enable an investigation of the effects of chemical agents in preventing tumour invasion or infiltration which is usually the first stage of dissemination. The technique of intracerebral tumour implantation is already in use as a system to detect agents which might prevent the systemic spread of the tumour. A subcutaneously transplanted tumour which leads to the formation of metastases in the lung is also used for the same purpose.

The conclusion of the meeting was that this important aspect of experimental cancer chemotherapy should be extended. Although it was agreed that the tests available at present were very few, there was every hope that new tests could be designed. In order to stimulate further interest in the subject the Experimental Chemotherapy Committee of the UICC plan to hold a symposium in 1969.

## Hormone Insecticides

from a Correspondent in Cell Biology

WILLIAMS and his collaborators at Harvard are doing some very exciting work which shows that insect juvenile hormone and naturally occurring and synthetic analogues can be used as a potent insecticide for the control of some very noxious insects. The group's latest finding (Vinson and Williams, *Proc. US Nat. Acad. Sci.*, **58**, 294; 1967) is that synthetic juvenile hormone

effectively blocks the hatching, metamorphosis and sexual maturation of the human body louse *Pediculus humanis*—a vector of epidemic typhus, trench fever and epidemic relapsing fever—which in many areas of the world has become resistant to virtually all the currently available insecticides.

Williams (1956) first recognized the potential value of juvenile hormone as an insecticide when he found that hormonally active extracts of certain moths cause lethal derangements of metamorphosis when applied to silkworm pupae. This was followed by the intriguing discovery (Sláma and Williams, 1965) that American, but not European, paper contained a natural analogue of juvenile hormone. The principal source of this material was eventually tracked down to pulp from the balsam fir *Abies balsamiae*, an indigenous American pulp tree. Law, Yuan and Williams (1966) then made a synthetic juvenile hormone of high activity which blocks the metamorphosis of the yellow fever mosquito *Aedes aegypti* (Riddiford and Williams, *Proc. US Nat. Acad. Sci.*, **57**, 595; 1967) as well as the human body louse.

In the current experiment, Vinson and Williams induced body lice to lay eggs on woollen or nylon pads impregnated either with synthetic juvenile hormone or, as a control, peanut oil. Only 24 per cent of the eggs on the hormone treated woollen pads hatched; none of those on the nylon pads but 82 and 88 per cent of the controls hatched. Moreover, if the female lice were exposed to hormone for more than 24 h before laying, none of the eggs laid on hormone impregnated pads hatched, whereas 85 per cent of the controls hatched.

Only 46 per cent of the eggs laid on unimpregnated pads by females given a 24 hour exposure before laying hatched, compared with 96 per cent hatching of eggs from females previously exposed to peanut oil. This effect, however, is shortlived. Eggs laid on unimpregnated pads more than 24 hours after the end of exposure of the females hatched successfully.

Synthetic hormone also prevents the normal development of nymphs. Up to the third instar, nymphs exposed to hormone behave like controls exposed to peanut oil. At this stage the controls undergo metamorphosis, become sexually mature and produce a new generation, but in striking contrast none of the nymphs exposed to hormone reaches sexual maturity.

Under laboratory conditions, synthetic juvenile hormone is obviously a very effective insecticide and ovicide. It will be of great interest to see whether these experiments can be scaled up to provide a commercially feasible method for the control of disease carrying insects. Significantly, the United States Army is a co-supporter of the work. Perhaps the greatest obstacle apparent from the experiments is that the effect of the hormone is so short-lived that the insects must be more or less continuously exposed to it.

## Pattern Vision after Lesions

from a Correspondent in Neurophysiology

Galambos, Norton and Frommer have now published results which show that even after extensive lesions to the optic tracts—severing up to 98.5 per cent of the fibres present—the cat is able to perform a visual form discrimination (*Exptl. Neurol.*, **18**, 8 and

26; 1967). Lesions were made electrolytically under stereotactic control; the illustrations show that they were well placed and that they destroyed at least as much tissue as was claimed. On the whole, there is little apparent damage to surrounding areas. Five cats with lesions destroying continuity of between 80 and 96 per cent of optic tract fibres on both sides were observed for visual deficits after the operation. Four were quite normal while one showed slight difficulty in manoeuvres involving vision.

Histological results obtained from these animals were used to guide lesion placements in a further three cats which were examined more thoroughly for visual defects in both flux discrimination and pattern discrimination. Animals were tested in a discrimination box for their ability to distinguish 6 from 9. One cat which had nearly all of both optic tracts destroyed between the chiasm and lateral geniculates learned by the fifth day after operation to make 40 out of 50 correct responses (29 of the last 30 were correct). The second, with lesions sparing only 3 per cent of fibres on one side, had reached the criterion of 90 per cent success within 350 trials before the operation, but afterwards could not at first see the choice panels. Eight days later, however, it began to show continual improvement above chance and gradually reached the 90 per cent criterion. The third cat, with no pre-operative training, reached criterion for a flux discrimination in two days, taking sixteen days for pattern discrimination. In a further group of six cats with lesions interrupting more than 99 per cent of the optic tracts, three with total lesions were blind, while three with no more than 1 per cent of optic tract fibres intact appeared blind in gross behavioural tests but none the less performed a flux discrimination 35 days after the operation. They were unable to re-learn a pattern discrimination.

The authors consider that these results are at variance with the apparently orderly structure of connexions within the visual system of the cat. But this is not particularly surprising. First, the capacity of the optic tract for transmitting information far exceeds the capacity of the brain for receiving it, if subsequent behaviour is considered to be determined only by the information processed. Many experiments on both human subjects and other mammals have clearly shown the limited capacity of the central nervous system for accepting information. Barlow, in the NPL symposium "The Mechanization of Thought Processes" (HMSO, 1958), gives a good discussion of redundancy in sensory systems. Secondly, we know that to establish recognition of an object it is not necessary for the same set of photoreceptors to be stimulated at each presentation. There is considerable size and orientation independence in pattern recognition: it is clear that the process of interest involves the central abstraction of features from a stimulus which may be conveyed from the periphery by a great number of paths. Within limits, it is not therefore essential that every pathway should maintain its integrity, and Galambos *et al.* give an estimate of these limits under the circumstances of their experiment. For the initial phase of an animal's life in which pattern recognition is learnt it is much more likely that the integrity of the visual pathway is necessary, but just as this learning involves recognition that many different stimuli can give rise to the same percept, so are there many ways of presenting the

necessary information for the performance of a visual discrimination. Lesions to the visual pathway must limit the number of ways in which a stimulus can be represented, but unless they are very extensive they need not effectively limit the rate of information transmission.

## Problems in Associating Systems

from a Correspondent in Molecular Biology

THE study of protein systems in which sub-units exist in association-dissociation equilibrium has come to have a fundamental interest in protein chemistry and enzymology. Many examples have recently come to light of situations in which the state of aggregation of the protein controls its function, and increasing attention has therefore been focused on the theoretical problems of analysing such systems by transport and equilibrium methods, notably sedimentation velocity and equilibrium, free boundary electrophoresis and partition chromatography. In all these processes the act of fractionation leads to the displacement of the equilibrium in a manner which is determined by the properties of the aggregated and disaggregated forms, the total concentration and the equilibrium constant(s) for the association. In principle it is possible to derive information about the stoichiometry, the equilibrium and the value of the equilibrium constant; the theory for such systems has been developed in general terms by Gilbert and others.

An article by Kegeles, Rhodes and Bethune (*Proc. US Nat. Acad. Sci.*, **58**, 45; 1967) now draws attention to a serious experimental source of error, hitherto completely overlooked, which may invalidate many of the results obtained on associating systems studied in the ultracentrifuge by sedimentation velocity. In high-speed sedimentation experiments a substantial hydrostatic pressure is generated, which can amount to hundreds of atmospheres towards the bottom of the cell. In aqueous systems, at least, this is insufficient to have more than a trivial effect on sedimentation velocities, but it can have a drastic influence on an equilibrium process. There is ample evidence that association processes are commonly accompanied

by an increase in molar volume, which can be observed by dilatometry. The application of pressure consequently leads to a displacement of the equilibrium towards the dissociated form. For realistic values of the molar volume of association, it turns out that the pressures generated in the ultracentrifuge at high speeds are sufficient to produce a substantial change in the equilibrium constant, which would therefore vary through the liquid column, and make analysis intractable. Kegeles *et al.* show that concentration distributions of quite misleading and unexpected shapes could be obtained, and evaluate some of the consequences of this situation.

In any event it appears clear at this stage that low-speed sedimentation equilibrium and partition chromatography ('Sephadex' gel filtration, for example) offer safer methods of studying such equilibria. The applicability of gel filtration has been discussed by Gilbert, Ackers and others, and a new analysis by Ackers (*J. Biol. Chem.*, **242**, 3026; 1967) has now appeared. Gel filtration involves a simple partition process of the molecules between the insides of the gel globules and the free solvent outside. The method has several experimental advantages, and Ackers has shown that dissociation constants may be determined even when the partition coefficients of the molecules are concentration-dependent. Although gel filtration provides probably the most advantageous approach to these equilibria, it cannot give molecular weights, except of an approximate nature, and sedimentation equilibrium is probably best used for this purpose. It is probable, however, that the increasingly firm theoretical foundation of the gel filtration technique, allied with its experimental precision and simplicity, will encourage widespread application.

An interesting example of the application of sedimentation equilibrium is the work of van Holde and Rossetti (*Biochemistry*, **6**, 2189; 1967) on the association of purine in aqueous solution (which presumably involves the stacking mechanism operative in polynucleotides). The results compare well with earlier studies by other methods, and support the conclusion that the aggregation process can be described by a single association constant. Thermodynamic parameters are derived.

## Steady State Crustal Spreading

by

PETER R. VOGT  
NED A. OSTENSO

Department of Geology,  
Geographical and Polar Research Center,  
University of Wisconsin,  
Madison, Wisconsin

Evidence which bears on the processes of continental drift, ocean floor spreading and the appearance of mid-oceanic rises is rapidly accumulating. The assumption that the mid-oceanic rises represent a steady state<sup>1,2</sup> leads to estimates of the rate of ocean floor spreading and of subsidence which in turn suggest geophysical tests of the theory.

### Crust

RECENT identification of the relationship between the observed symmetric magnetic anomaly patterns across mid-ocean ridges<sup>4</sup> and magnetic field reversals during the

past  $3.4 \times 10^6$  yr B.P.<sup>5</sup> has provided a unique method of determining ocean floor spreading rates. Vine<sup>6</sup> determined rates of 0.95 cm/yr for the Mid-Atlantic Ridge south of Iceland, 1.9 cm/yr at 38° S., 4.4 cm/yr for the East

Pacific Rise at  $51^\circ$  S., and 2.9 cm/yr for the Juan de Fuca Ridge, while Pitman and Heirtzler<sup>7</sup> determined a spreading rate of 4.5 cm/yr for the Pacific-Antarctic Ridge. Thus it appears that crustal spreading rates vary along the length of the mid-ocean ridge system by at least a factor of four. This longitudinal variation in velocity may distort the usual parallelism of the anomaly pattern associated with mid-ocean ridges<sup>7</sup>. The magnetically determined spreading rates determined for the Atlantic Ocean are plotted as a function of latitude in Fig. 1.

Fig. 1. Variation of drift rate with latitude in the Atlantic Ocean. Closed circles are computed from island ages<sup>11,12</sup>, and latitude of island is plotted. Vertical bars at  $33^\circ$  N. and  $38^\circ$  S. are due to uncertainty in age of Madeira, and distance of Tristan da Cunha from axis, respectively. Open circles are computed from magnetic anomalies<sup>6</sup>. Horizontal bar indicates upper limit of drift rate for North American Basin<sup>13</sup>. Crosses are drift rates and latitudes of oldest cores<sup>13</sup>. Solid curves are expected variation of drift rate if rifting began at  $120 \times 10^6$  yr B.P.<sup>9</sup> (a) or  $260 \times 10^6$  yr B.P.<sup>8</sup> (b), and is proportional to east-west width of Atlantic Ocean. Dotted curve is variation if rate is proportional to east-west width of mid-Atlantic ridge, and edges of ridge are  $50 \times 10^6$  yr B.P. isochrons.

Besides these magnetic data there is other evidence for longitudinal variations in crustal spreading rates. Such evidence includes the ages of sediment cores from the ocean floor; geological evidence of continent separation; variation in width of mid-ocean ridges; the age of islands as a function of distance from the axis of the Mid-Atlantic Ridge; and the occurrence of numerous lateral offsets along oceanic ridges.

From the ages of sediment core J. Ewing *et al.*<sup>8</sup> have concluded that rifting of the Atlantic floor began at least  $260 \times 10^6$  yr in the region of the North American Basin. If spreading has progressed at a constant rate since initial rifting, the region  $20^\circ$ – $40^\circ$  N. is moving at 1.2 cm/yr. This value is plotted as a horizontal bar in Fig. 1. In contrast, King<sup>9</sup> has used geological evidence to argue that the separation of South America and Africa was initiated about  $120 \times 10^6$  yr ago. Again assuming no temporal variations, the average spreading rate for the South Atlantic would then be 2.5 cm/yr.

If, on the other hand, simultaneous east-west separation of the American-Eurafrican rift is taken as a constraint, then the variation in width of the Atlantic Ocean should directly reflect longitudinal variations in crustal spreading rates. Using the above two starting dates of 120 and  $260 \times 10^6$  yr B.P. as illustrative examples of synchronous rifting, variations in spreading rate of the Atlantic as a function of latitude are as plotted in Fig. 1.

The width of a segment of the mid-ocean ridge may also be a measure of its rate of spreading. This follows if crestral and abyssal depths are relatively constant, mid-ocean ridges are steady-state features for periods of  $10$ – $50 \times 10^6$  yr and subsidence of the flanks is to first approximation only a function of time after extrusion at the axis.

The variation of ridge width in the Atlantic Ocean is plotted as a function of latitude in Fig. 1. The datum for this curve was arbitrarily taken to be the magnetically

determined drift rate of 0.95 cm/yr (ref. 6) south of Iceland. The curve is seen to pass through the other magnetically determined drift rate of 1.9 cm/yr at  $38^\circ$  S.<sup>6</sup> and roughly reflects the variation of spreading rates computed from island ages<sup>10</sup> discussed below. Available data<sup>6</sup> indicate that the generally wider East Pacific Rise is also spreading more rapidly.

The contention that the width of a mid-ocean ridge is related to the spreading rate is readily tested by detailed magnetic surveys, for the width of anomalies should then vary inversely with the regional slope. Pitman and Heirtzler<sup>7</sup> have analysed magnetic anomalies over the Pacific-Antarctic Ridge and the Reykjanes Ridge to get crustal spreading rates. From their data it follows that (a) for at least the last  $3.4 \times 10^6$  yr the spreading rate has been 1 cm/yr for the Reykjanes Ridge and 4.5 cm/yr for the Pacific-Antarctic Ridge. (b) Spreading has been linear with time, and thus with distance, at least out to the  $3.4 \times 10^6$  yr isochron on both ridges. This corresponds to a distance of 34 km from the axis of the Reykjanes Ridge and 153 km from the axis of the Pacific-Antarctic Ridge. Because the magnetic signature of the two ridges can be matched by linear adjustments of horizontal scale, it appears that spreading is linear out to 100 km on the flanks of the Reykjanes Ridge and 500 km on the Pacific-Antarctic Ridge flanks<sup>7</sup>. This supports the suggestion that the spreading rate increases gradually with distance from the rift axis<sup>14,15</sup> only if the rate of increase is proportionately equal at the areas compared. (c) Estimates from Pitman and Heirtzler's<sup>7</sup> Figs. 2, 3 and 4 give an average subsidence rate to the  $10 \times 10^6$  yr isochron of about 10 cm/ $10^3$  yr for both the Reykjanes and Pacific-Antarctic Ridges, if these ridges are assumed to have been steady-state for the last  $10 \times 10^6$  yr. Comparison of these two ridges thus suggests that ridge width is related to spreading rate.

Wilson<sup>10</sup> first plotted radiometrically determined ages of islands in the Atlantic Ocean against distance from the axis of the ridge. The data<sup>11</sup> (Fig. 2) suggest a general increase of age with distance, thus supporting the hypothesis that islands form near the crest and drift away at the rate of a few cm/yr. Because the oldest rocks may not have been sampled the indicated drift rates represent upper limits (unless some of the volcanic islands originated on the ridge flanks rather than at the axis of rifting<sup>2</sup>).

If the dated rocks originated at the axis of rifting and the drift rate has been constant with time, from Fig. 1 it seems that spreading rates are low at the northern and southern extremities of the Mid-Atlantic Ridge but exceed 2 cm/yr in the regions  $20^\circ$ – $40^\circ$  N. and  $10^\circ$ – $40^\circ$  S. The two drift rates calculated from magnetic anomalies<sup>6</sup> are in rough agreement with the drift rates determined from island ages.

Some of the scatter in Fig. 2 may be due to the assumption that spreading has been east-west from the rift axis. Suppose instead that the islands were carried away from the axis of the Mid-Atlantic Ridge along flow lines suggested by Carey<sup>12</sup>. These flow lines are the trajectories along which continents have supposedly separated. In Fig. 3 the oldest core and island dates<sup>10</sup> have been replotted as a function of distance from the rift axis along the flow lines. These distances were scaled to an estimated accuracy of about  $\pm 5$  per cent.

If rifting began simultaneously throughout the Atlantic, then the drift rate of a unit of the ocean floor should be proportional to the total length of the flow line passing through it and extending from the rift axis to the edge of the continent. Fig. 4 shows the same data as Fig. 3 but plotted against a dimensionless number which is the ratio of distance from the axis to total length of the flow line. These attempts to reduce the scatter on Fig. 2 do not conclusively demonstrate either that drifting began simultaneously or that the spreading rate has been constant in time.

The paleontologically determined ages of some pre-

Fig. 2. Age of oldest rock from various islands in the Atlantic Ocean, plotted against distance from axis of mid-Atlantic ridge<sup>11,22</sup>. Solid circles indicate active volcanoes; bars indicate uncertainty in age or distance from axis of ridge.

Pleistocene sediment cores from the Atlantic have been plotted against distance from the mid-Atlantic Ridge (Fig. 5)<sup>13</sup>. By dividing these ages into their respective distances from the ridge axis the average drift rates can be estimated. Data for some of the oldest cores (with the lowest drift rates) are plotted in Fig. 1. The average drift rates range from 1 to 2 cm/yr and, despite the sparse data, there is a faint suggestion of a maximum at 34° N. Because the sediments sampled at each locality are not necessarily the oldest, the calculated drift rates are upper limits. The drift rates implied by sediment ages appear significantly lower than those computed from island ages. As the islands are generally further from the axis, there are at least two interpretations also consistent with magnetic data<sup>6,7</sup> which show an increase of anomaly wavelength several hundred km from the axis (about  $10 \times 10^6$  yr at spreading rates of a few cm/yr): (a) spreading is steady state, with velocity increasing gradually away from the axis<sup>14,15</sup>; or (b) spreading rates were higher in the past and diminished about  $10 \times 10^6$  yr.

If the width of a mid-ocean ridge is a measure of the rate of spreading, then changes in ridge width ought to be marked by transverse faulting. Such changes in ridge width are observed, for example, in the equatorial Atlantic and north of Iceland. Transverse fractures occur in the same regions. Inspection of the physiography of the Atlantic Ocean might lead to the supposition that transverse fracture zones are somehow required by changes in direction of ridges. The mid-ocean ridge curves around the southern end of Africa without significant offsets, however.

If rifting began roughly synchronously in the Atlantic Ocean, the present variation in ocean width implies that, at least in the past, spreading rates have varied along the ridge. This variation in spreading rate is not, however, valid if the ocean crust has been moving at a greater rate than continents, that is, if down welling convection cells have existed along the margins of the Atlantic Ocean. If this were the case (assuming synchronous rifting) the spreading rate could have been constant along the length of the Atlantic, with most intense down welling occurring where the ocean is at present narrow, for example, in the Greenland Sea. There is no geological evidence, however, to suggest active Tertiary trenches in that area.

There is evidence that rifting may not have been synchronous in the Atlantic. Non-synchronous rifting rules out the possibility that the continents have been displaced and rotated as rigid wholes, and requires some tectonic deformation on land, regardless whether the oceanic crust is moving faster than the continents or not. The limiting case of a longitudinally constant spreading rate would mean a direct correlation between width of ocean and age. This would mean that the north equatorial Atlantic was of mid-Mesozoic age, the South Atlantic of late Mesozoic, and the Arctic Atlantic of Tertiary age. Such a rifting model implies tectonic deformation on the adjacent continents, especially in regions where the ocean narrows abruptly such as between 40° N. and 50° N. and between 70° N. and 80° N. in the Atlantic. A correlation between terrestrial tectonics and ocean floor spreading history, as

Fig. 3. Age of seventeen oldest sediment cores and islands in the Atlantic Ocean<sup>10</sup> plotted against distance ( $x$ ) from axis of mid-Atlantic ridge as measured along flow displacement lines<sup>12</sup>. A dashed line which indicates drift rate of 2.5 cm/yr has been added for reference.

Fig. 4. Same ages as above, plotted against  $X/D$ , where  $D$  is distance along flow displacement line<sup>12</sup> from mid-Atlantic ridge to edge of continent, and passing through dated points. If rifting began simultaneously at  $120 \times 10^6$  yr, and proceeded along flow lines, all points would lie above dashed line.  $D$  varies from less than 500 km (Greenland Sea) to over 5,000 km (Florida).

unravelling by magnetic anomalies, may discriminate among these hypotheses. Until then a longitudinal variation of spreading rate, at least in the past, appears most reasonable.

It has also been suggested<sup>14,15</sup> that spreading velocity may increase gradually away from the axis. This possibility places another perturbation on ocean floor displacement which will be considered later.

### Steady-state Model

If the flank profile of a mid-ocean ridge is constant with time the ridge can be considered a steady-state feature. Suppose that material wells up in the central region of a ridge and spreads laterally, sinking at a rate which does not vary with time for a given distance from the axis.

Let  $y$  denote distance measured along the length of the ridge, and  $x$  the distance from the axis measured along the trajectory of spreading. If spreading proceeds essentially at right angles to the crest, the regional slope at a point  $P(x,y)$  on a steady-state ridge will be  $\tan^{-1} S(x,y)/f(x,y)$ , where  $S$  denotes the spreading velocity and  $f$  denotes the rate of subsidence. According to the linear spreading hypothesis of Dietz<sup>1</sup> and Hess<sup>2</sup>,  $S(x,y)$  would be constant with respect to  $x$ . In this case the topographic slope at a point would uniquely determine the subsidence rate  $f(x,y)$ . If, however,  $S(x,y)$  increases gradually from zero at the crest to a maximum value somewhere on the flanks<sup>11,13</sup>, the spreading rates plotted in Fig. 1 are average values, always less than the actual spreading rate at the point  $P(x,y)$  considered. Therefore, division of the average spreading rate by the local slope will yield a lower limit for local subsidence rate. If the elevation of mid-ocean ridge crests above abyssal levels is taken as nearly a constant the width of ridges is then inversely proportional to the average regional slope of the flanks. Therefore, a wide ridge could mean either rapid spreading or slow sinking. In the preceding discussion evidence was given that  $S(x,y)$  varies at least by a factor of four in the  $y$  direction. Consider now whether or not  $f$  is constant with time, that is, does it vary with  $x$ ? Sinking of a unit of ocean floor with time could be caused by a number of processes including chemical changes involving change in volume, isostatic settling or thermal contraction caused by progressive cooling of mantle material spreading away from the axis of upwelling.

Langseth *et al.*<sup>3</sup> computed ridge profiles on the assumption that hot material ascends at the axis, spreads laterally at a uniform rate, and contracts as it loses its heat through the Earth's surface. Their data shows that the average subsidence rate ( $f$ ), independent of  $S$  if  $S > 0.5$  cm/yr, is about 2.5 cm/1,000 yr for the first  $50 \times 10^6$  yr. This agrees closely with the subsidence rate determined from various atolls and guyots (Fig. 6). Nevertheless Langseth *et al.*<sup>3</sup> think that crustal spreading has not been operative on the Mid-Atlantic Ridge since the beginning of Tertiary time, except possibly during the last few million years. This conclusion is based on the absence of a broad heat flow maximum which their model predicts. However, they admit that if mantle material ascends over a broad

Fig. 5. The ages of sediment cores<sup>13</sup> as a function of distance from the axis of the mid-Atlantic ridge. Vertical bars indicate uncertainty of the absolute dates associated with stratigraphic dates of cores. Straight line indicates uniform drift rate of 2.5 cm/yr.

Fig. 6. Subsidence plotted against time<sup>3,7,10-12</sup>. Curve B is the average subsidence rate due to the thermal contraction model<sup>3</sup>. Curve A represents average actual subsidence rate on upper flanks of Reykjanes and Pacific-Antarctic ridges, if the ridges are steady-state features. Note that curves A and B represent subsidence as a function of time after extrusion, whereas the other data are a record of subsidence looking backwards in time.

region and then spreads at a rate which gradually increases with  $x^{14,15}$ , or if there is an insulating surface layer which is not perfectly coupled to the flow, then the expected heat flow maximum would be much reduced. Further, they acknowledge that available data permit spreading of the East Pacific Rise as an admissible hypothesis.

To examine the thermal expansion model in greater detail an example of a smoothed profile from part of the mid-ocean ridge is shown in Fig. 7, in which the crestal elevation for the theoretical profile has been selected to give the best fit to the observed profiles. The dashed horizontal line indicates the theoretical equilibrium datum, that is, the abyssal plain at great distances from the axis, and after sediments have been removed.

Although Langseth *et al.*<sup>3</sup> reject this model on the basis of observed heat flow across the Mid-Atlantic Ridge there are three points of similarity between the theoretical and actual mid-ocean ridges: the calculated subsidence rates are 2.5 cm/10<sup>3</sup> yr (curve B, Fig. 6) which compares with rates of 10 cm/10<sup>3</sup> yr for the Reykjanes and Pacific-Antarctic Ridges (curve A, Fig. 6) and 2 cm/10<sup>3</sup> yr for the average subsidence of atolls and guyots during the last 50–100 × 10<sup>6</sup> yr; the calculated elevation of the crest above the abyssal plain is about 2 km (independent of  $S$  for  $>0.5$  cm/yr), which compares favourably with actual ridges; the calculated regional slopes (out to at least 550 km from the crest) compare favourably with actual slopes on mid-ocean ridges, with the best fit corresponding to an  $S$  of 1 or 1.5 cm/yr.

If thermal expansion contributes to the elevation of mid-ocean ridges, then at least spreading rates should be reflected in the width of heat flow anomalies. Unfortunately, data are not yet adequate to confirm this relationship along the Mid-Atlantic Ridge. It appears, however, that the heat flow anomaly is wider over the East Pacific Rise where spreading is faster<sup>6,7</sup>. For instance the width of isothermal belts enclosing values of heat flow exceeding 3  $\mu\text{cal}/\text{cm}^2/\text{sec}$  is 600 km over the East Pacific Rise<sup>16</sup> and no more than 200 km over the Mid-Atlantic Ridge<sup>17</sup>. Thus the assumption that the elevation of ridge crests is caused by thermal expansion, or conversely that the subsidence of flank slopes is caused by cooling contraction seems valid.

Langseth *et al.* took the surface conductivity as representative of the upper 100 km of the Earth. To reconcile the observed  $f$  of 10 cm/10<sup>3</sup> yr across the Reykjanes and Pacific-Antarctic Ridges to their calculated  $f$  of 2.5 cm/10<sup>3</sup> yr requires that conductivity increases with depth.

Rapid subsidence would imply rapid cooling and thus higher conductivity. For a given spreading rate higher conductivity would narrow the predicted heat flow maximum, but the ridge profile would be narrowed as well. We have found that the 1 cm/yr spreading model best fits the profiles of the average mid-ocean ridge. Therefore, if this fit is to be retained while the conductivity is increased in such a way as to multiply  $f$  by 4, then  $S$  must also be multiplied by 4. The required spreading rate is then about 4 cm/yr which is the order of observed  $S$  for the East Pacific Rise. These changes in  $S$  which are required by the observed  $f$  would presumably leave the dimensions of the heat flow anomaly essentially unchanged. Thus, a mere change in conductivity cannot reconcile the model of Langseth *et al.* with the fact that the Mid-Atlantic Ridge and the East Pacific Rise have similar profiles but dissimilar heat flow anomalies. A thermal model must be sought which incorporates the known difference in crustal structure as well.

### Subsidence of Oceanic Islands

Independent estimates of the subsidence rate  $f$  may possibly be derived from the sinking of atolls and guyots in the Pacific. Islands may form at the axis of a mid-ocean ridge and ride down the continuously foundering "conveyor belt" toward the abyssal plains<sup>2</sup>. As soon as vulcanism ceases, wave erosion begins to truncate the seamount, and further sinking will produce a guyot. Maximum subsidence possible on this hypothesis will be for an island formed and truncated on the crest, which is on the average 2–3 km deep and 2–3 km above the abyssal plains. For a guyot on the abyssal plain, the subsidence can then be no greater than 2–3 km. Actually the equilibrium level will be somewhat deeper after the sediments have been removed. Total subsidence might be as great as 4–5 km if basement depths under continental rises of the Atlantic Ocean are interpreted at least partly in terms of subsidence from the crests of mid-ocean ridges. Lesser depths to the tops of guyots which now rise from abyssal depths could be a result of islands retaining their

Fig. 7. Smoothed profiles<sup>14,15</sup> across the mid-Atlantic ridge, between 22° N. and 38° N., compared to the thermal contraction models<sup>3</sup>. Dotted curves are model profiles for 1 cm/yr (steeper profile) and 2 cm/yr drift rates<sup>8</sup>. Dashed curve is a pure exponential, shown for comparison.

volcanic activity for some distance as they were carried down the flanks, or of islands formed somewhere on the flanks<sup>2</sup>. The present existence and even volcanic activity of Atlantic islands now hundreds or thousands of km from the axis of the mid-ocean ridge suggests that "late truncation" is possible (see Fig. 2).

If sinking of the flanks is caused by thermal contraction of ascended mantle material spreading from the axis of a ridge, the sinking rate of a parcel of oceanic crust may be only a function of time after extrusion. In that case, should convection cease, the mid-ocean ridge will subside as it cools, and a parcel of crust containing the guyot will continue sinking at the same rate as when the ridge was still "active". The total subsidence after convection ceases will then depend on the distance  $x$  of the guyot from the axis, and can be no greater than the height of the crest of an active ridge above the abyss, namely, 2 or 3 km. Menard<sup>18</sup> has argued that many of the guyots in the southwestern Pacific were associated with a Late Cretaceous rise, now totally subsided (Darwin Rise). There are many other guyots, however, not thought to be related to extinct rises. We suggest that the subsidence rates should be the same whether the island rode down the flanks or subsided as part of a dying ridge. According to the present hypothesis the time for a seamount to sink 2–3 km should be comparable to the time required for material from the crest to reach the outer flanks of an active ridge. If the sinking rate of islands should prove to be greater than the rate of subsiding of flanks, or if guyots with tops much deeper than 3 km can be found, regional subsidence does not suffice, and it would be necessary to suppose that sea level has risen, or that subsidence relative to the crust has taken place. It should be noted that subsidence rates estimated from islands, unlike those determined from the flanks of mid-ocean ridges and discussed previously, are subject to the additional uncertainty of sea level changes. If there is no discrepancy in these two estimates of subsidence, large changes in sea level can be ruled out.

Hamilton<sup>19</sup> has studied the sinking seamount problem in detail and concludes that sinking, not a gradual rise in sea level, is the dominant process involved. A plot of dated depths from guyots and atoll bore holes<sup>20</sup> is shown in Fig. 6. The average subsidence rate has been about 2 cm/10<sup>3</sup> yr for at least the last 60 × 10<sup>6</sup> yr. Two guyots (1 and 2 in Fig. 6) suggest a levelling off in the subsidence rate from 60 to 100 × 10<sup>6</sup> yr after sinking began. Because of the uncertainty in age (the depth being precisely known), the range in average subsidence rates may be as great as 1.5–5 cm/10<sup>3</sup> yr.

Guyots and atolls are rare in the Atlantic. Shallow-water carbonates were encountered in a deep borehole on Andros Island<sup>21</sup>, however, and these are plotted in Fig. 6. The subsidence rate of Andros Island is the same (2 cm/10<sup>3</sup> yr) obtained for Pacific atolls and guyots. The oldest horizons on Andros Island may have suffered additional depression from thick sedimentary overburden, but since at least 60 × 10<sup>6</sup> yr ago there appears to have been no significant difference between the sinking rates of the guyots, which are free of sediment, and the atolls.

The sinking rate of seamounts has therefore been of the same order (1–5 cm/10<sup>3</sup> yr) but lower than the subsidence of the upper slopes of the Pacific–Antarctic Ridge and the Reykjanes Ridge. Subsidence on the latter ridges has been 10 cm/10<sup>3</sup> yr for the last 3–4, and probably the last 10 × 10<sup>6</sup> yr, if those ridges are steady-state features. This subsidence rate has been added to Fig. 6 (line A). Let us try to account for the difference between ridge and island rates of sinking. First, it is reasonable that the initial subsidence rate should be higher than the average over many tens of millions of years because  $f(x)$  must be a decreasing function. Second, it is possible that cessation of volcanic activity and truncation of an island often did not occur until the island had been carried some distance away from the crest, that is, to a region where the sinking

rate was less. Some of the guyots and atolls may have long since ceased their subsidence so that the average rate is much lower than the actual rate. Less likely explanations for the difference in subsidence rates are that the flanks of the Pacific–Antarctic and Reykjanes Ridges are sinking unusually rapidly, or that the time scale of magnetic reversals is too short by a factor of about four, or that sea level has been falling at about 8 cm/10<sup>3</sup> yr, or that the ridges are not steady-state features.

Let us apply the proposed model to two of the few dated guyots presently near an active ridge. First, Erben Guyot rises from abyssal depths west of southern California, about 1,500 km from the supposed axis of the East Pacific Rise. A truncated top submerged 750 m has been dated as Miocene (10–25 × 10<sup>6</sup> yr)<sup>20</sup>. These data are combined with an average ridge profile in Fig. 8. The average subsidence rate must lie between 3 and 7 cm/10<sup>3</sup> yr, which is, and should be according to the present model, less than the initial rate of 10 cm/1,000 yr discussed above. If the seamount drifted down the flanks of a typical ridge, it must have been truncated at about half the present distance to the axis of the ridge (Fig. 8). Let us assume a value of 3 cm/yr based on a magnetically determined drift rate of 2.9 cm/yr for the Juan de Fuca Ridge<sup>6</sup>. Then Erben Guyot was truncated at 25 × 10<sup>6</sup> yr, which is consistent with the Miocene age determined for its top. If this former island originated at the crest of the ridge, it must have been active between about 25 and 50 × 10<sup>6</sup> yr ago. This consequence of the hypothesis could be checked with isotope dating of dredge basalt from the guyot.

Guyots among the Tuamotu Islands have been dated at 40–45 × 10<sup>6</sup> yr (Fig. 8). Their tops are submerged 900 m and are about 2,700 km from the axis of the East Pacific Rise, or about 2,000 km from their possible location on the flanks when they were truncated. Taking the drift rate of about 4.5 cm/yr determined recently<sup>6,7</sup> for the Pacific–Antarctic Ridge, the time since truncation of the Tuamotu guyots should be 2,000 km/4.5 cm/yr, or about 44 × 10<sup>6</sup> yr. This compares perhaps too well with the Upper Eocene data obtained for their tops. Menard<sup>18</sup> would ascribe the sinking of the Tuamotu guyots to the subsidence of an ancient ridge, the Darwin Rise. Hess<sup>2</sup> has suggested that the crest of the entire Pacific Ocean was generated at the axis of the Darwin Rise. According to those hypotheses the above agreement in ages of truncation would have to be fortuitous.

If regional subsidence down the flanks of the East Pacific Rise correctly explains the submergence of the as yet undated Pratt–Walker group in the Gulf of Alaska, the ages of truncation should increase from east to west because the tops are concordant (700–800 m) and the slope of the sea floor slight. If sinking has been local, or a result of a rise in sea level, there would be no reason to expect such an increase of age from east to west, and a sinking rate of 2 cm/10<sup>3</sup> yr would suggest a common age of 40 × 10<sup>6</sup> yr for the group of guyots. If the guyots came from the Darwin Rise<sup>2</sup> they must be still older. But Pratt guyot, for example, is only about 500 km from the axis of the ridge, so that according to the present hypothesis its top must be younger than 16 × 10<sup>6</sup> yr. Drift rates inferred from magnetic anomalies, and dating of the guyot tops will decide the question.

The interpretation of the subsidence of guyots in the Mid-Pacific Mountains and the Bikini–Eniwetok group is more complicated, as they might be related to the Melanesian Rise, the East Pacific Rise, the extinct Darwin Rise, or to several of these features.

The uniformity of sinking rates for widely separated atolls and guyots of different sizes suggests that the foundering is regional, not local. According to the present hypothesis, the total subsidence cannot exceed the height of a mid-ocean ridge above the abyssal plain (after sediments have been removed), which generally does not

Fig. 8. Origin and subsidence of Erben and Tuamotu guyots<sup>20</sup> according to hypothesis<sup>2</sup> that subsidence is result of drifting down the flanks of average mid-ocean ridge. All elements except guyot flanks are drawn to scale. Note that fossil ages from guyot tops agree closely with ages computed from distance travelled after truncation, and crustal spreading rates determined from magnetic profiles in the vicinity of the seamounts. Erben Guyot is at 34° N., while a 2.9 cm/yr drift rate was established at 49° N.<sup>6</sup>. The Tuamotu Guyots are at 15° S., while a 4.5 cm/yr drift rate was established between 40° S. and 55° S.<sup>7</sup>.

exceed about 3 km. Fig. 6 shows that this is the case for the limited number of features so far dated. Unfortunately there could be another possible explanation for the absence of subsidence much greater than about 3 km. The oldest dates are about  $100-200 \times 10^6$  yr, which is the order of time required to sweep the ocean basins clear of seamounts at spreading rates of a few cm/yr. Thus depths greatly exceeding about 3 km are not likely to occur, regardless of how the seamounts are sinking.

### Continental Shelves

Pre-Cretaceous erosional surfaces dip seaward under several shelves bordering the Atlantic Ocean. Two boreholes drilled through the wedge of younger sediments east of Cape Hatteras yield a record of subsidence at about the same rate (a few cm/ $10^3$  yr) as that of Andros Island, Eniwetok and Bikini atolls, and a number of guyots in the Pacific. In Fig. 6, the subsidence curves for the North Carolina Esso No. 2 and the Hatteras No. 1 boreholes have been constructed from the data of Heezen<sup>22</sup>. It is tempting to suggest that the same mechanism of regional contraction is involved in the subsidence of guyots, atolls, banks, and mid-ocean ridges themselves.

The subsidence of shelves on rifted coast lines (where there are no trenches) may be incorporated into the hypothesis of mid-ocean ridge formation if we make two suppositions: the erosional surface which dips seaward under the wedge of Mesozoic and younger sediments was formed when Eurafica and the Americas were at the stage of rifting represented by the East African rift belt of today; erosional lowering of this pre-Atlantic uplift was rapid enough to remove several km of material in the highest, steepest region along the axis of the uplift before significant lateral spreading had occurred. It then follows that, as the severed continental edges withdrew from the axis of uplift and subsided, an initially nearly level surface could acquire a seaward dip. In areas where the erosion had been sufficiently active, subsidence could lower the land below sea level, where it began to receive sediment in Cretaceous and later times. Isostatic loading and compaction could then account for still further depression of the shelves.

If this view is correct, then the material eroded from the pre-Cretaceous uplift must have been carried eastward into Eurafica and westward into the Americas, although some of the sediment would have been trapped in axial graben valleys. Erosion must have been in rough proportion to the elevation, so that the axial zone of greatest uplift was most deeply eroded. Therefore, a series of boreholes penetrating the pre-Cretaceous basement would be expected to encounter generally older rocks under the edge of the shelf than nearer to the continent. The Cretaceous and younger sediments should thicken seaward, and the deeper units should dip more steeply. This is known from boreholes on the Atlantic coastal plain and continental shelf<sup>22</sup>. The slope of the pre-Cretaceous erosional surface should be comparable to or less than the regional slope of mid-ocean ridges (if equilibrium has been reached). The basement slopes seaward at about 20 : 1,000 east of Cape Hatteras<sup>22</sup>. This compares with 2 to 10 : 1,000 for typical mid-ocean ridges (Fig. 7). Therefore, either the initial uplift was steeper, or isostatic depression and compaction have steepened the dips. The widths of subsiding shelves should be comparable to or less than half the width of mid-ocean ridges. Inspection of any chart of the Atlantic Ocean reveals this to be the case. If the edges of rifted continents have no shelves at all, the implication is that erosion was inadequate compared to the initial uplift and the rate of rifting. In any case there should be evidence for some subsidence since rifting began, and, conversely, coast lines that have not been rifted should be free of shelf-wedges. A maximum subsidence of at least 3 km and possibly 4-5 km could be accounted for in this manner. Greater subsidence is indicated by seismic refraction, but has not been proven by boreholes, for the basement under the edge of the shelf off eastern North America<sup>21</sup>. In some areas the basement has been located as much as 8 km below sea level, but it is not proven that the seismic interface can be identified as the same pre-Cretaceous erosional surface penetrated by boreholes nearer the present shoreline, such as the two boreholes plotted in Fig. 6; and Heezen *et al.*<sup>22</sup> have linearly extrapolated the borehole data seaward and found that benches in the

continental slope can be related to specific Tertiary rock formations. This suggests that the seismic discontinuity which forms depressions underneath the outer parts of the shelves and the continental slope is an older surface. Is this downbuckling an isostatic effect, a buried trench, or even a buried rift valley that did not widen into an ocean?

By analogy to present East Africa it would appear that several branches of the rift may have existed before formation of the Atlantic Ocean. Perhaps the offshore depressions in the basement are, like the Triassic lowlands (Newark Series), grabens filled with non-marine clastics and eruptive rocks. Whatever the final answer to this problem, it appears that a substantial part of the subsidence of shelves may be related to the same mechanism (thermal contraction by cooling?) that causes the flanks of mid-ocean ridges to subside. Alternatively, the depression of continental margins has been linked to descending limbs of convection cells, and the buried grabens identified as marginal trenches which once resembled the present Puerto Rico Trench<sup>21,22</sup>.

Fig. 6 suggests that subsidence has continued into geologically recent times. It may be objected that subsidence of the basement under Andros Island and the continental shelf should have ceased long ago, as these features are presently over 3,000 km from the ridge axis. The abyssal plains slope toward the continents after sediments have been removed, however, suggesting that equilibrium has not been reached. Further, if thermal contraction is the mechanism, it follows that the mantle under the oceanic crust seaward of the shelf has come closer to thermal equilibrium than adjacent shelves. This follows because the shelves both insulate the mantle and supply some radiogenic heat of their own. Thus the continental edges may continue to subside after the adjacent abyss has reached equilibrium. For some unknown interval of time after rifting the abyss contracts more rapidly than the immediately adjacent shelf. This process may contribute to keep the shelf edge abrupt.

Theoretical calculations such as ref. 3 can explore this possibility.

## Conformation of the Anticodon Loop in tRNA

by

W. FULLER  
A. HODGSON

Biophysics Department and  
MRC Biophysics Research Unit,  
King's College, University of London

A molecular model for the anticodon arm is proposed which is compatible with chemical, X-ray and genetic evidence. It provides a stereochemical basis for Crick's "wobble" hypothesis.

NUCLEOTIDE sequences determined for a number of amino acid specific tRNA molecules<sup>1-4</sup> have led to the suggestion that these molecules have a "clover leaf" structure (Fig. 1). This was because, despite their different nucleotide sequences, there are striking structural homologies when the tRNA molecules are folded so that the number of intramolecular Watson-Crick base-pairs is a maximum (Fig. 1). Diagrams like Fig. 1, however, indicate little of the three-dimensional appearance of such structures and their implications. Therefore we have constructed three-dimensional models, and here describe a molecular model-building study of the anticodon arm.

Using chemical information about nucleotide sequence and X-ray evidence on the conformation of base-paired regions in the tRNA, the maintenance of reasonable stereochemical constraints leads to a model for the anticodon arm. This model accounts for the observed

degeneracy in the reading of the third position of the codon and also makes a prediction about the site of the distortion required to accommodate this degeneracy.

### Model Building Technique

We used Corey, Pauling and Koltun<sup>5</sup> spacefilling models and also skeletal models with a scale of 4 cm to 1 Å (ref. 6). The former ensure that short van der Waals contacts are avoided during preliminary investigations. Because, however, the atomic centres in them are inaccessible, we used skeletal models when preliminary study suggested that a particular conformation merited detailed analysis. Lengths and angles of covalent bonds and short van der Waals contacts were calculated from atomic co-ordinates measured on skeletal models and the co-ordinates were adjusted until acceptable stereochemistry was obtained,

that is lengths of covalent bonds within 0.05 Å of accepted values, covalent angles within 6° and no non-covalently bonded contacts more than 0.4 Å short of the sum of the atomic van der Waals radii. We do not necessarily believe that our models describe the actual molecular conformations to an accuracy of a few hundredths of an angstrom, but the analysis shows that a model with the general characteristics we propose can be built with acceptable stereochemistry. Only if model building is treated as a rigid discipline with strict attention paid to detailed stereochemistry can the results of a study such as this be considered reliable and meaningful.

### Conformation of the Anticodon Arm

X-ray diffraction suggests that the molecules of tRNA (ref. 7), in common with all RNA molecules so far studied by this method, contain helical regions with a conformation similar to that determined for two-stranded reovirus RNA (ref. 8). We have assumed that the Watson-Crick base-paired regions in the clover leaf structure have a conformation like the eleven-fold double-helical structure of reovirus RNA (rather than the less favoured ten-fold possibility). In the anticodon arm there is a loop of seven nucleotides at the end of the helical region. From considerations of biological function, the structural homologies in the different tRNA species might be expected to extend to the conformation of this loop.

The characteristic features of polynucleotide secondary structure are provided by interbase hydrogen bonding and base-stacking. The tRNA nucleotide sequences so far determined do not suggest an intramolecular base-pairing scheme which would give a similar structure for all the anticodon loops (Fig. 2). Therefore we searched for conformations of this loop which maximized single-

Fig. 1. Generalized clover-leaf structure for yeast tRNA based on sequences determined for tRNAs specific for alanine<sup>1</sup>, serine<sup>2</sup>, tyrosine<sup>3</sup> and phenylalanine<sup>4</sup>. A base-pair is indicated by a line linking two parts of the RNA chain (a dashed line indicates a base-pair occurring in some tRNAs but not in others); X indicates a nucleotide which varies with the tRNA species; nucleotides which occur at an equivalent position in all sequences are denoted as follows—uracil (U), dimethylguanine (DMG), adenine (A), cytosine (C), thymine (T), pseudouracil (ψ). The number at the centre of each loop indicates the number of nucleotides in the loop.

Fig. 2. The nucleotide sequences in yeast tRNA anticodon loops. The anticodon is shown boxed. The symbols ψ, MeI, C, G, I, U, A, IPA, DiMeA, Y, OMeG, OMeC stand for respectively: pseudouracil, 1-methyl-inosine, cytosine, guanine, inosine, uracil, adenine, isopentenyl-adenine, dimethyl-adenine, a so far unidentified purine, O-methyl guanine, O-methyl cytosine. (The references from which the sequences were taken are in the caption to Fig. 1.)

stranded base-stacking. In doing this we also attempted to: (a) avoid negatively charged phosphate groups coming closer to each other than in accurately determined crystalline fibrous structures; (b) ensure that hydrogen bond donor groups on unpaired bases and ribose sugars were not buried in the structure, so they were unavailable for hydrogen bonding; (c) maintain single bond orientations in the polynucleotide chain (for example, the conformation at the glycosidic link) within the limits of values observed in model compounds and other polynucleotides.

When these stereochemical constraints are maintained, model-building studies suggest that the polynucleotide chain has surprisingly little conformational freedom. Furthermore, orientation of the single bonds in the only two polyribonucleotides whose structures have been determined in detail by X-ray analysis (two-stranded helical RNA (ref. 8), and two-stranded polyadenylic acid<sup>9</sup>) are rather similar. Therefore if stacking is to be maintained, the polynucleotide chain might be expected to have a conformation similar to that in one of the structures described for ribopolynucleotides. Stacking as much as possible of the anticodon loop on top of the double helical region of the anticodon arm might be expected to "nucleate" the structure of the single-stranded region so that its nucleotide conformation is similar to that in the double helical region, that is that of the eleven-fold model for reovirus RNA. (We refer to this conformation as standard.) There is some support from physical studies on solutions of polynucleotides and dinucleotides for postulating that the conformation of a single-stranded polynucleotide with base-stacking is similar to the conformation it would have as one of the strands in a two-stranded structure<sup>10,11</sup>.

Figs. 3 and 4 illustrate the structure which stacks the greatest number of the nucleotides in the anticodon loop. Five nucleotides are stacked in the standard conformation so that they lie on the same helix as that chain in the anticodon arm double-helix nearer the tRNA 3' end. This structure represents a unique solution to the problem of maximizing base-stacking in the anticodon loop. Conformations with slightly different base tilt and rotation and translation of each nucleotide (for example if the standard nucleotide conformation was that of the ten-fold rather than eleven-fold RNA model) could of course give a similar degree of base-stacking. Stacking combinations of nucleotides other than those stacked in this structure, however, result in less than five nucleotides being stacked. In particular five nucleotides cannot be arranged so that they lie on the same helix as that chain of the anticodon arm double-helix nearer the tRNA 5' end. This is shown in Fig. 4 where A and B are closer together than they would be for a structure with bases perpendicular to the helix axis. If, however, the five bases were stacked on the chain of the two-stranded helix nearer the tRNA 5' end, the base tilt would make the distance to be spanned by the two non-standard nucleotides greater than for a structure with bases perpendicular to the helix axis. In addition to this increased distance, the two nucleotides would have to span the RNA groove containing the 2-keto

groups rather than that containing the 6-keto groups which is spanned in the model illustrated in Figs. 3 and 4. The RNA conformation is such that spanning the groove containing the 2-keto groups requires a much longer polynucleotide chain.

In the structure illustrated in Figs. 3 and 4 the two nucleotides of the anticodon loop not in the standard conformation have the planes of their bases approximately parallel, with some overlap of their hydrophobic surfaces. There is, however, some flexibility in this region of the structure and this conformation should be regarded as typical of a number of related possibilities. All the tRNA nucleotide sequences so far determined are compatible with the poorer stacking of these two nucleotides as compared with that in the standard helix because these bases are always pyrimidines (of which at least one is uracil). These bases are generally thought to stack least well. In all these sequences, the second of the five nucleotides in the single stranded helix (that is 7 in Fig. 4) has a chemically modified hydrogen bonding donor group on the base. In addition to inhibiting base-pairing which might favour alternative structures to that in Figs. 3 and 4, this group may increase hydrophobic stabilization of this stacked conformation.

The structure illustrated in Figs. 3 and 4 could describe the conformation of the loop of 7 unpaired bases in the T $\psi$  loop (Fig. 1). The occurrence of uracil and cytosine, however, at what would be positions 6 and 7 in the single-stranded helix (Fig. 4) make it a rather less attractive solution than it is for the anticodon loop.

A loop at the end of an RNA double helix need be no longer than three nucleotides<sup>12</sup>. The base-stacking in such a structure, however, is probably much less perfect than that in the standard conformation and such a loop would only be expected to occur if it contained nucleotides with poor stacking interactions, for example the loop with UUU and UCU at the end of the extra arm in the two serine tRNAs (Fig. 1).

### Codon-Anticodon Interactions

From consideration of the likely anticodon in a number of tRNAs and a knowledge of the different codons which will

Fig. 3. Schematic diagram of the model for the tRNA anticodon arm illustrating its relationship to the codon. The helical regions are shown as straight in this diagram. CD is the first base-pair in the double helical region of the anticodon arm and all the bases between A and C are stacked on one another and follow a regular helix. The companion set between B and D and the set of three bases in the codon follow the complementary helix. In space (see Fig. 4) A and B are quite close together because five nucleotide pairs is about half a turn of the helix.

Fig. 4. Schematic diagram of the tRNA anticodon loop illustrating its relationship to the codon and the helical character of the structure. The letters A, B, C and D identify the same points on the structure as in Fig. 3. The bases in nucleotides 1 to 10 are stacked on one another and follow the regular helix which is shown black. The chain of the anticodon double helix between D and B is shaded like the codon to indicate that they follow the same helix. This helix is complementary to the black one. The two nucleotides not in the standard conformation are represented by dark line shading. The representation of their conformation is very schematic because they lie behind nucleotides 8, 9 and 10 in the black chain. The dotted lines indicate the generic helix from which the structure can be imagined to be derived.

recognize a particular tRNA species, Crick<sup>13</sup> has proposed a hypothesis for codon-anticodon recognition. This involves standard Watson-Crick base-pairing between the bases in the codon and anticodon triplets while allowing the possibility of "wobble" or limited alternative pairing in the third position. When codon and anticodon are paired in this way, the atomic sequence in one chain is the reverse of that in the other and the two triplets can be arranged as the two strands in a regular RNA double helix. In our model the anticodon triplet occupies positions 8, 9 and 10 of the anticodon helix (Figs. 3 and 4) and a messenger RNA (mRNA) codon can be base-paired to it without steric hindrance between the rest of the anticodon arm and adjacent mRNA codons. In fact simultaneous recognition of two anticodon arms by adjacent codons is stereochemically possible (Fig. 5). There is not much flexibility in the relative position and orientation of two anticodon arms when they are interacting simultaneously with adjacent mRNA codons. They can interact, however, with each other in a way similar to neighbouring helices in crystalline fibres of reovirus RNA (ref. 8) (see caption to Fig. 5). The possible biological significance of intermolecular hydrogen bonds between the sugar hydroxyl of one helix and the phosphate oxygen of another has been noted<sup>8</sup>. One such hydrogen bond is formed between the two anticodon arms when arranged as in Fig. 5. Preliminary studies suggest that it is possible to arrange the clover leaf arms of the generalized tRNA molecule (Fig. 1) so that there is no steric hindrance between two tRNA molecules whose anticodon arms are interacting in this way.

It might be asked if mistakes in translation could occur by codon "recognition" of bases at positions 7, 8 and 9

Fig. 5. Schematic diagram of successive codons in mRNA simultaneously recognizing anticodon arms. Each codon of the mRNA has the conformation illustrated in Figs. 3 and 4. The operation required to move the anticodon arm from the amino-acid site to the peptidyl site involves a rotation  $\theta$  about and a translation  $t$  along the anticodon helix axis and a translation  $d$  perpendicular to the helix axis along a line joining the two helix axes illustrated in this figure. If the anticodon helices are linked by a hydrogen bond and have a stereochemical relationship like two reovirus RNA helices in the crystalline fibre then the symmetry operation can be defined precisely as follows (otherwise it is an approximate description).  $\theta = 87.3^\circ$  (that is  $120-32.7$ ),  $t = -2.73$  Å,  $d = 22$  Å. Values of  $\theta$  and  $t$  which would move nucleotide 9 into the position occupied by nucleotide 10 (Fig. 4) are taken as positive.

(or even 6, 7 and 8) rather than 8, 9 and 10 of the anticodon helix. Studies with spacefilling models suggest that recognition of both 7, 8 and 9 and 6, 7 and 8 could not be excluded even if it is insisted that adjacent codons recognize anticodon arms simultaneously. Recognition of 6, 7 and 8 is the less plausible stereochemically. If the geometry of the tRNA-mRNA-ribosome interaction is inadequate to prevent mis-reading of this kind, it may be that it is prevented by the chemical modification which occurs at nucleotide 7 (Fig. 4) in all sequences determined so far<sup>1-4</sup>.

### Stereochemical Aspects of the "Wobble" Hypothesis

We have considered possible distortions of our model for codon-anticodon interaction which would accommodate the alternative base-pairings described by Crick in his "wobble" hypothesis<sup>13</sup> (Table 1). The separation and relative orientation of the glycosidic links in these alternative base-pairs differ from that in the standard Watson-Crick pairs. The position of the wobble base-pair in our model is illustrated in Figs. 3 and 4. Accommodation of adenine-inosine in this position requires extension of the sugar-phosphate chain linking the second and third bases of the anticodon (at positions 9 and 10) or compression of the chain joining the second and third bases of the codon. The chain in the RNA helix is already rather compressed (about 5.6 Å between successive phosphates as compared to about 7 Å in a completely extended chain) and further compression results in steric hindrance between the 2' hydroxyl (and the sugar carbon to which it is attached) and the base of the previous nucleotide. Therefore the principal distortion involved in accommodating adenine-inosine (and any other alternative pairs with an interglycosidic link separation larger than the standard pair) must occur at the anticodon.

In contrast accommodation of an alternative pair with an interglycosidic link separation smaller than the standard pair would require either extension of the sugar-phosphate chain between the second and third bases of the codon or compression of the chain between the second and third bases of the anticodon. Significant compression of the chain can be excluded, and so it appears that the principal distortion involved in accommodating pairs with

an interglycosidic link separation significantly shorter than standard must occur at the codon.

### Site of Distortion in "Wobble" Pairing

Using skeletal models we have found that all the alternative pairing required to account for the genetic evidence on degeneracy in the third position of the codon-anticodon interaction can be accommodated in our model by distortion of the anticodon alone (Table 1). Distortion of the codon conformation is not required. Further, our model building studies indicate that a uracil-uracil pairing can be accommodated if distortion is allowed at the codon. Therefore, because the genetic evidence excludes such pairing in this position, we can conclude that it does not occur because the codon conformation cannot be significantly distorted. It should be noted, however, that our criteria for an acceptable pairing relate to the geometry of the interbase hydrogen bonds and the stereochemistry of the sugar-phosphate chain. While these are clearly necessary requirements, other considerations may also be relevant to the occurrence of a particular alternative pair, for example interbase dipole-dipole interactions. (It may be that non-occurrence of the uracil-uracil pair is the result of such effects rather than of the codon being rigidly held.)

The assignment of "wobble" distortion to the anticodon rather than the codon seems reasonable from general considerations because one might expect each codon to be held on the 30S ribosome in a way which is independent of its position in the mRNA and therefore through bonds involving groups near to or part of the sugar-phosphate chain of the codon currently being read. Such bonds would be expected to limit the conformational flexibility of the codon as compared with the anticodon (which is a relatively small part of the tRNA molecule and not necessarily close to the ribosomal binding site on the tRNA) in a way which is compatible with the above assignment of the distortion

Table 1. THE ACCOMMODATION OF ALTERNATIVE BASE-PAIRS AT THE "WOBBLE" POSITION IN THE CODON-ANTICODON COMPLEX AS A FUNCTION OF WHETHER THE DISTORTION IS ALLOWED IN THE CODON OR ANTICODON CONFORMATION

Alternative codon-anticodon pairs (groups involved in interbase hydrogen bonding)	Genetic evidence for its occurrence (— denotes occurrence) (X denotes non-occurrence)	Stereochemistry of the polynucleotide chain according to the site of distortion (— denotes acceptable stereochemistry) (X denotes unacceptable stereochemistry)	
		Distortion at anticodon only	Distortion at codon only
Adenine-inosine (6-amino to 6-keto and N1 to N1)	—	(The torsion angle of the inosine glycosidic link is about $5^\circ$ outside the acceptable range)	X
Guanine-uracil (6-keto to N1 and N1 to 2-keto)	—	(There is a hydrogen-oxygen non-bonded contact of about 2.2 Å, i.e., about 0.3 Å less than the sum of the van der Waals radii of these atoms)	X
Uracil-guanine (N1 to 6-keto and 2-keto to N1)	—	(There is a hydrogen-oxygen non-bonded contact of about 2.2 Å, i.e., about 0.3 Å less than the sum of the van der Waals radii of these atoms)	X
Uracil-uracil (6-keto to N1 and N1 to 2-keto)	X	X	X
Uracil-uracil (N1 to 6-keto and 2-keto to N1)	X	X	—
Uracil-cytosine (6-keto to 6-amino and N1 to N1)	X	X	X

For none of the pairings denoted as "stereochemically acceptable" is the stereochemistry quite as satisfactory as that in the undistorted standard conformation. The departures from acceptable stereochemistry are noted and are small enough for it to be concluded that the codon-anticodon complex could be distorted to accommodate these pairs. In contrast the stereochemistry of the pairs denoted "stereochemically unacceptable" is quite unacceptable with non-covalently bonded contacts 1 or 2 Å less than normal values and with torsion angles 40 to  $50^\circ$  outside the range of observed values.

associated with "wobble" pairing to the anticodon. Further, the occurrence of the "wobble" base at the top of the single strand anticodon helix allows distortion in the part of the sugar-phosphate chain to which it is attached to be absorbed in the conformational flexibility of the two unstacked pyrimidines next to it.

The model we propose for the anticodon arm of tRNA allows codon-anticodon interaction through Watson-Crick base-pairing. The codon and anticodon nucleotide triplets have the conformation of the two strands in a regular RNA double helix. The alternative or "wobble" pairings suggested for the third base of the anticodon can be accommodated in this model by distortion of the anticodon conformation. It is not necessary to postulate distortion of the anticodon conformation. The observation that uracil-uracil is not a wobble pairing suggests that codon conformation distortion does not take place. This model of the anticodon arm allows adjacent mRNA codons to simultaneously recognize anticodon arms.

In a study such as this it is important to identify clearly the principal assumptions on which the model building is based. Essentially the only assumption we make is that the number of stacked bases in the anticodon loop should be a maximum; this leads to a unique solution for the conformation of the loop. The model receives support from the base sequences which have been determined for the anticodon loop in a number of tRNAs (Fig. 2): the pyrimidines (mainly uracil) are in the irregular part of the loop, the wobble base is at that position in the stacked part of the structure which has the most conformational

flexibility, and the modified purine is at a position which could prevent a wrong set of three nucleotides in the anticodon being recognized by the codon. There is no structural or genetic evidence in conflict with this model and, while the model building study does not prove it to be correct, its stereochemical neatness and the manner in which it accounts for what is known about the anticodon region of tRNA suggest that it is essentially correct.

One of us (A. H.) is the holder of a Medical Research Council award. We thank Professor Sir John Randall, Professor M. H. F. Wilkins, and Dr F. H. C. Crick for their interest, Miss A. Kernaghan for preparing the figures and Mr Z. Gabor for carrying out photographic work.

## Aetiology of Multiple Sclerosis

by  
JOSEPH BERNSOHN  
LEO M. STEPHANIDES

Neuropsychiatric Research Laboratory,  
Veterans Administration Hospital,  
Hines, Illinois, and  
Department of Biochemistry,  
Northwestern University Medical School,  
Chicago, Illinois

Are dietary defects a cause of multiple sclerosis? There is some evidence that a lack of certain fatty acids during the maturation of the brain results in demyelination.

ONE hypothesis of the aetiology of multiple sclerosis is that the disease is a result of a dietary deficiency of polyunsaturated fatty acids (PUFA). Sinclair<sup>1</sup> concluded that the diets of civilized countries were becoming deficient in these fatty acids and thought that one sequela of such a deficiency could be demyelination of the nervous system. Swank<sup>2</sup> has suggested that multiple sclerosis is the result of the ingestion of a diet rich in animal fats deficient in polyunsaturated fatty acids. These two concepts may not be incompatible, because a low saturated fat intake may cause a sparing of these fatty acids<sup>3</sup>. In areas of the world where there is a high incidence of multiple sclerosis (Northern United States, Central and Northern Europe), a dietary deficiency of polyunsaturated fatty acids is unlikely to occur, and this makes it unlikely that such a deficiency is a cause of the disease.

At least two of the polyunsaturated fatty acids, namely, linoleic and linolenic acid, have different biological functions<sup>4</sup>. In the animal organism, the biosynthesis of polyunsaturated fatty acids proceeds along two independent metabolic pathways<sup>5,6</sup>. Longer chain  $\omega$ 6 series acids are synthesized from  $\Delta$ 9,12 linoleic acid (18 : 2  $\omega$ 6) as a precursor. (The  $\omega$ -number is designated in reference to the

position of the double bond starting from the methyl end of the molecule.)  $\alpha$ -Linolenic acid (18 : 3  $\omega$ 3) is required for the biosynthesis of the longer chain  $\omega$ 3 fatty acids. The interconversion of  $\omega$ 6 and  $\omega$ 3 series acid does not appear to occur in the animal organism<sup>7</sup> or in developing chick brain<sup>8</sup>.

The two principal polyunsaturated fatty acids in mammalian<sup>9,10</sup> and chick brain<sup>11</sup> are arachidonic (20 : 4), an  $\omega$ 6 acid, and docosahexaenoic (22 : 6), an  $\omega$ 3 series acid. These acids are found primarily in the glycerophosphatides and more specifically in the phosphatidylethanolamine (PEA) and phosphatidylserine (PS) fractions, with lesser amounts in phosphatidylcholine (PC). Rathbone<sup>12</sup> found 8.6 per cent and 11.4 per cent of the total fatty acids of rat brain consisted of 20 : 4  $\omega$ 6 and 22 : 6  $\omega$ 3, respectively. In the fully developed chick embryonic brain, 20 : 4 constituted 13.5 per cent, 4.1 per cent and 3.8 per cent of the total fatty acids of the PEA, PS and PC fractions, respectively. The comparable values for 22 : 6 were 19.8 per cent, 26.2 per cent and 1.1 per cent<sup>13</sup>. O'Brien and Sampson<sup>14</sup> found that 20 : 4  $\omega$ 6, 22 : 5  $\omega$ 6 and 22 : 6  $\omega$ 3 were present at a relatively high level in PEA and PS in human brain. It is apparent that the

brain cephalin fraction is relatively rich in  $\omega 6$  and  $\omega 3$  series polyunsaturated fatty acids.

The composition of brain fatty acids may be influenced by the fatty acid composition of the diet. This relationship has been demonstrated in chickens<sup>15</sup>, young rats<sup>16</sup> and older rats<sup>12</sup>. Feeding 18:2 leads to an increase in longer chain  $\omega 6$  acids and feeding 18:3 to an increase in  $\omega 3$  series acid, and so Mohrhauer and Holman concluded that at least one member of each family of polyunsaturated fatty acids must be able to pass through the blood-brain barrier (this term is used in a functional sense in further discussion). Lipid-soluble substances are known to penetrate the blood-brain barrier more readily than most aqueous-soluble compounds<sup>17</sup>, and Sperry *et al.*<sup>18</sup> have determined that labelled octanoic acid can penetrate the blood-brain barrier.

Usually 18:2 constitutes about 1 per cent of the fatty acids in the brain<sup>19</sup>, and this fatty acid pool may be utilized for the biosynthesis of longer chain  $\omega 6$  polyunsaturated fatty acids. There is a slow turnover of phospholipids in adult brain<sup>20</sup> and so the brain may be able to survive any 18:2 deficiency in the diet for extended time periods. In our work with chicks, however, as well as those already cited with mammalian species, virtually no brain phospholipid 18:3 could be detected. In the absence of any pool of 18:3, any requirements for this  $\omega 3$  fatty acid would seem to depend on an adequate exogenous source. If the intake of polyunsaturated fatty acids is less than marginal during development, subsequent requirements for  $\omega 3$  acids as a result of normal turnover cannot be met. Alternatively, the structure of developing nervous tissue formed during periods when an adequate exogenous source of  $\omega 3$  acids is unavailable may be defective and break down after an extended time period.

The known stability of myelin and the low turnover of myelin lipids<sup>21-23</sup> may seem inconsistent with the foregoing concept. The same studies, however, demonstrated that the turnover of the lecithin and cephalin fractions is greater than that of spingomyelin, cerebrosides or cholesterol. It should be borne in mind that there may be a relative deficiency of  $\omega 3$  acids early in life, and perhaps even *in utero*, on a diet deficient in  $\omega 3$  fatty acid. The margin of safety involved here is unknown. In addition, the primary metabolic lesion may not occur in myelin, but demyelination may be a secondary effect of abnormal metabolism in other brain structures; for example, neurones, glia or neuronal processes. Thus Terry and Harkin<sup>24</sup> indicated in Wallerian degeneration that the periodic layers of myelin were intact at a time when the axoplasm and mitochondria are damaged. Another factor to be considered is the relatively late time of peak onset of the disease (about 30 yr) (ref. 25), a fact which may be compatible with the slow myelin lipid turnover.

Experimental data which tend to support the concept of  $\omega 3$ -deficiency have been reported. Weil<sup>26</sup> reported a decrease of phospholipids in the brain in multiple sclerosis. Gerstl *et al.*<sup>27,28</sup> found deficits in phospholipids and fatty acids in intact white matter from brains of patients with multiple sclerosis. They also reported that the lipid content of myelin from such brains was less than that of the control. Kishimoto *et al.*<sup>29</sup> analysed the fatty acids of glycerophospholipids from apparently normal white matter derived from patients with multiple sclerosis, and reported that the 22:6  $\omega 3$  content of the ester-linked fatty acids was less than half of that found in normal white matter. The number of cases thus far reported is too small to permit generalizations to be made. Lecithin from the white matter of patients with multiple sclerosis contains a larger percentage of saturated fatty acids than that of control subjects<sup>30</sup>. Analysis of the cerebrospinal fluid phospholipids in multiple sclerosis<sup>31,32</sup> has shown that a relative increase in the cephalin fraction occurs and the severity of the clinical picture has shown a good correlation with the increase in cerebrospinal fluid cephalin. A group of patients with multiple sclerosis studied

by Tourtelotte *et al.*<sup>33</sup> gave results which can be recalculated in units used by McArdle and Zilkha to show a similar trend. No determinations for polyunsaturated fatty acids were attempted in these studies. Other phospholipid fractions were normal.

The two principal dietary sources of the  $\omega 3$  fatty acids are a variety of seed and marine oils<sup>34</sup>, the latter rich in polyunsaturated  $C_{20}$ - and  $C_{22}$ -acids. Differences in species and environmental conditions influence the  $\omega 3$  fatty acid content but the following generalizations may be made<sup>34</sup>. Edible seed oils with a significant 18:3 content are found in soybeans, whole wheat, millet, a number of nut and fruit oils, and some non-edible seeds yield oils which are used for cooking in many parts of the world; for example, linseed and rapeseed. In addition, a wide variety of vegetable and fruit oils indigenous to tropical and sub-tropical climates contain 18:3 as a minor component. Marine oils have a high content of  $C_{20}$ - and  $C_{22}$ -unsaturated fatty acids, while oils from fresh water fish contain  $C_{18}$ -unsaturates<sup>35</sup>. Cod-liver oil is reported<sup>36</sup> to contain 0.7 per cent 18:3 and 8.7 per cent 22:6. The fish oils of the sardine, herring, menhaden and mackerel are rich in  $C_{20}$ - and  $C_{22}$ -unsaturates. The principal site of lipid storage in fish is the liver<sup>37</sup> and the amount present in extra-liver sources depends on the nutritive condition and the species. It appears that where the whole fish is consumed, an increased supply of  $\omega 3$ -type acids would be available. The ready anti-oxidizability of these highly polyunsaturated fatty acids is relevant to fish oils. Drying of the fish, lengthy exposure to air, and excessive cooking would cause peroxidation or polymerization of the essential fatty acids and make the amount of protective factor available uncertain.

The difficulties of studying the epidemiology of a low-incidence disorder like multiple sclerosis has already been detailed by McAlpine, Lumsden and Acheson<sup>38</sup>, and the citations that follow refer to the page number in their treatise. If the known epidemiological data are correlated with the distribution of foods containing fatty acids of the linolenic acid type, the following points can be made.

(a) In North America, Europe, the Near East and probably Australia and Asia (except for Japan and China) there appears to exist a north-south gradient, with the incidence of the disease lower in warmer latitudes (p. 43). This low incidence occurs in areas where the consumption of animal protein is generally low and where there is an availability of a large variety of seed and fruit oils, in many cases dietary staples, which contain small to moderate amounts of 18:3. Thus the use of palm oil in the tropics, millet in parts of Asia, safflower, cottonseed and rapeseed oils, as well as berries and fruits containing 18:3 in warm latitudes, could be preventive of multiple sclerosis.

(b) The low incidence of multiple sclerosis in Japan (p. 5) and China (p. 27) may be attributed to the widespread use of soybeans in the diet as well as the availability of marine foods in many cases eaten uncooked, which would tend to preserve the content of polyunsaturated fatty acids.

(c) There are variations in the patterns of distribution of multiple sclerosis in the high incidence area of Central and Northern Europe. Where statistics are available (Scotland and Norway) they indicate that high incidence areas involve "... remote, circumscribed or mountainous tracts of country where there may be special problems such as ... lack of variety in the diet" (p. 32). Thus in Norway (p. 48) the disease is uncommon in coastal fishing areas and common in interior agricultural communities. Sallstrom<sup>39</sup> found the incidence of the disease high in agricultural workers in Sweden.

(d) Whether the incidence of the disease differs in urban versus rural areas is not well documented (p. 32). Miller *et al.* (p. 38) have suggested that in England and Wales the risk of the unskilled worker developing multiple sclerosis was half that of someone in the professional or

managerial class. This may be a reflexion of economic status and the tendency to substitute animal protein for fish and vegetable proteins by the more affluent. In a study of Army inductees, Beebe *et al.*<sup>40</sup> concluded that the incidence of multiple sclerosis was higher in metropolitan or urban areas when compared with rural areas.

(e) Migration from a high risk zone to a low risk zone carries with it in part the risk of the country of origin (p. 39). Migration from a low risk to a high risk area may increase risk (p. 40). Other variables, however, such as age at the time of migration, obscure any definitive assessment. In a study of immigrants to Israel originating from Europe and Afro-Asia, Alter<sup>41</sup> found no change in the low incidence of the disease in the latter group. In Europeans under 15 yr old at immigration, the incidence of the disease approached that of the Afro-Asians, indicative of a protective effect of migration. In Europeans migrating at 15–29 yr the incidence was 8.9 times the Afro-Asian, and at 30–44 yr this figure was 5.4. The authors remark that their data indicate that multiple sclerosis is acquired many years before the onset of clinical symptoms, and the early life history of the patient might be examined for an aetiological factor. Older people, however, may be habituated to dietary preferences and the statistics may reflect a resistance to changes in food selection with age.

(f) The tendency for the disease to be familial (p. 61) is explicable on the dietary deficiency hypothesis. Mackay and Myrianthopoulos<sup>42</sup>, in an investigation of monozygotic and dizygotic twins, concluded that if genetic effects are involved in the aetiology of multiple sclerosis they are subjected to powerful environmental influences.

The problems that present themselves in advancing this hypothesis are numerous.

(a) The inability to produce demyelination of the nervous system in experimental animals on an  $\omega 3$  fatty acid-deficient diet may be the result of either differences in specie sensitivity or the inability of animals to survive such a diet for the period of time required to produce lesions. Much of the experimental work reported on a linolenic acid deficiency has involved a deficiency of polyunsaturated fatty acids.

(b) The data on the composition of polyunsaturated fatty acids in the brain in multiple sclerosis is limited. It will require more detailed analysis of various lipids and lipid fractions before any assessment of the effect of deficiency of these acids can be made.

(c) Some of the epidemiological data cited indicating partial protection in the young in moving from a high risk to a low risk area suggest some exogenous requirement before the brain matures.

(d) There may be other unknown metabolic pathways where a requirement exists in the absence of any precursor pool. Thus the aetiology of multiple sclerosis may reside in more than one dietary deficiency. Alternatively, the dietary intake of  $\omega 3$  fatty acids may be adequate but the pathway from ingestion to the final deposition of 22:6 in the brain may be impaired. Thus absorption from the gastro-intestinal tract, transport mechanisms in the blood, passage across the blood-brain barrier, or the  $\omega 3$  elongation system, may be defective in patients who develop multiple sclerosis. We have shown in chick brain<sup>43</sup> that the elongation of 18:3  $\omega 3$  to 22:6  $\omega 3$  may proceed with a regulatory mechanism different from that of the  $\omega 6$  acids. Multiple sclerosis may thus be a result of some aberration in the control mechanism of 18:3 elongation to 22:6 resulting in an apparent deficiency in brain concentrations of the latter. Competition has been demonstrated between 18:2 and 18:3 and Rahm and Holman<sup>44</sup> showed in rats that an increase in the intake of 18:2 depressed the concentrations of 22:6 in liver fatty acids. We have found that the incorporation of <sup>14</sup>C-linolenic acid into 22:6 in brain slices was markedly inhibited by the presence of  $\Delta 6,9,12$  6 isomer of linolenic acid (unpublished results of Stephanides and Bernsohn).

(e) It has been pointed out<sup>45</sup> that monomolecular surface films of fatty acids are influenced by unsaturation. Unsaturated acids produce films of the expanded type, and as the double bond moves toward the methyl end of the molecule, the film expands more readily. Thus a deficiency of  $\omega 3$  fatty acids in the membrane may produce a more rigid structure which may not be consistent with normal functioning in the central nervous system.

Many basic data need to be obtained before the theoretical aspects of this problem can be fully elucidated. Such data and the development of an animal model would be a desideratum but the nature of the clinical problem and its seriousness for the patient and family has prompted this presentation despite the apparent gaps in knowledge.

We thank Dr Kevin D. Barron, head of the Neurology Service, Veterans Administration Hospital, Hines, Illinois, for his help.

This work was supported by the Veterans Administration and by a grant from the National Multiple Sclerosis Society.

The position and magnitude of the optically active absorption bands in the non-haem iron proteins xanthine oxidase and spinach ferredoxin are found to be very similar. A study of the Cotton effects in these proteins suggests that xanthine oxidase contains four identical pairs of iron atoms while spinach ferredoxin contains only one pair.

SPINACH ferredoxin (photosynthetic pyridine nucleotide reductase), isolated from the chloroplasts of spinach leaves, acts as an electron carrier in photosynthesis<sup>1,2</sup>. It contains two atoms of iron per mole<sup>3,4</sup>, undergoes reversible oxidation and reduction and only one electron is transferred per mole in the process<sup>3,4</sup>. By contrast, bacterial ferredoxin contains about six atoms of iron per mole and two electrons are transferred per mole in the oxidation-reduction process<sup>5,6</sup>. These two proteins can, however, be interchanged in the reduction of triphosphopyridine nucleotide using chloroplast extracts free of ferredoxin<sup>7</sup>.

Xanthine oxidase from mammalian milk has a function and size different from those of the ferredoxins. It contains about eight atoms of iron, two atoms of molybdenum and two moles of flavin adenosine dinucleotide (FAD) per mole<sup>8</sup>; up to ten electrons are transferred per mole in the oxidation-reduction process<sup>9</sup>. It has, however, an electronic spectrum rather similar to that of spinach ferredoxin.

The optical properties of bacterial ferredoxin have been previously studied as have those of rubredoxin (a red non-haem iron protein isolated during the purification of bacterial ferredoxin and containing one iron atom per mole)<sup>10,11</sup>. We now present a similar study of spinach ferredoxin, parsley ferredoxin and xanthine oxidase.

Spinach ferredoxin was kindly provided by Professor F. R. Whately, and parsley ferredoxin by Dr H. E. Davenport. Measurements on these proteins were carried out in 0.05 molar *tris*-hydrochloric acid buffer pH 7.4. Xanthine oxidase was purified according to a procedure developed by Drs L. I. Hart and R. C. Bray (unpublished), based on the observation<sup>8</sup> that salicylate treatment selectively denatures enzymes free of molybdenum. The specific activity/ $E_{450}$  of the enzyme used was 153 and it had iron : FAD : molybdenum : enzyme ratios of 7.2 : 1.7 : 1.7 : 1. (Dr L. I. Hart kindly prepared and analysed the enzyme for us.) The enzyme was stored at 4°C in molar phosphate buffer (pH 6) containing 3 mmolar sodium salicylate and 1 mmolar EDTA. Measurements were carried out in 0.055 molar pyrophosphate buffer (pH 8.2) containing 1 mmolar EDTA. Methanol-inactivated xanthine oxidase was prepared by the dialysis method using salicylaldehyde as substrate<sup>12</sup>. The reduced spectra

were obtained by adding crystalline sodium dithionite to the samples of spinach and parsley ferredoxins; aeration restored the original oxidized spectra. Xanthine oxidase was reduced by adding a calculated amount of xanthine dissolved in 0.02 molar sodium hydroxide to give approximately a 10 molar excess of substrate or by adding a solution of sodium dithionite in 0.001 molar sodium hydroxide again to give a 10 molar excess. Special anaerobic heads for both the circular dichroism and optical rotatory dispersion cells were used. The procedure for anaerobic addition has been described previously<sup>13</sup>. In other experiments, reduction of xanthine oxidase was accomplished by adding solid dithionite; this procedure gave identical results to those where the addition of sodium dithionite was controlled. Samples of xanthine oxidase were transferred anaerobically from the circular dichroism cells to electron spin resonance tubes and the state of oxidation of the flavin, molybdenum and iron studied<sup>14</sup>.

The Cotton effects of spinach ferredoxin are shown in Fig. 1 and those of xanthine oxidase in Fig. 2. Measurements from these spectra are given in Tables 1 and 2 together with those of other non-haem iron proteins. The results are presented in molecular form using a molecular weight of 274,000 (ref. 14) and  $E_{1\text{cm}}^{1\%}$  of 2.4 (ref. 8) at 450 mμ for xanthine oxidase and a molecular weight of 13,000 (ref. 3) for spinach ferredoxin. The present results are in essential agreement with the previous studies of the rotatory dispersion of these proteins<sup>15-18</sup> over a limited wavelength range and also with the more informative property, circular dichroism, of oxidized xanthine oxidase (Keleti, T., unpublished results).

Despite the widely differing composition and molecular weights of the two proteins, it is evident that the spectra of the oxidized forms are very similar in the region 350–800 mμ with the exception of a positive circular dichroism maximum at about 600–640 mμ in spinach ferredoxin. Thus it is clear that the spectra are produced by similar chromophores in similar asymmetric environments. In spinach ferredoxin this chromophore can only arise from the two iron atoms, and similar iron atoms must also constitute the visible chromophores in xanthine oxidase. The molybdenum atoms therefore do not contribute appreciably to the observed spectra in the visible region

Fig. 1. The optical properties of spinach ferredoxin. *A*, Absorption; *B*, circular dichroism; *C*, optical rotatory dispersion; —, oxidized; . . . , oxidized (8 molar urea); ---, reduced.

except perhaps at about 600 mμ. Similarly the flavins, which have an absorption band at 450 mμ, give rise to little if any optical activity. These flavin molecules must therefore be in a site of low asymmetry.

A comparison of the intensities of the circular dichroism spectra from oxidized xanthine oxidase and spinach ferredoxin (Table 1) reveals that over the wavelength range 400–800 mμ the values for xanthine oxidase are about four times the corresponding values for spinach

ferredoxin. The slight differences in the positions of the absorption maxima are reflexions of differences in the primary, secondary, or tertiary structure of the protein bound to the chromophore.

Fig. 2. The optical properties of xanthine oxidase. *A*, Absorption (at wavelengths below 300 mμ the scale is five times reduced); *B*, circular dichroism (at wavelengths below 250 mμ the scale is one hundred times reduced); *C*, optical rotatory dispersion (at wavelengths below 300 mμ the scale is five times reduced); —, oxidized; . . . , reduced with xanthine; ---, reduced with dithionite; — · — · —, oxidized "Flavin-Mo" free enzyme (replotted from the data in ref. 19).

\* Sources and comments as in Table 1.

Fig. 3. The variation of the circular dichroism of spinach ferredoxin with temperature: —, 1° C; ---, 22.5° C; ···, 32.2° C. This sample contained a polyphenolic impurity giving rise to the large negative effect at 300 mμ.

It has been found that in FAD and molybdenum-free xanthine oxidase, the extinction coefficient (at 450 mμ) is 5,000 cm<sup>2</sup> moles<sup>-1</sup> (ref. 19) per iron; this agrees well with that calculated by Bray<sup>20</sup>. Using this value, the contribution of FAD and molybdenum to the molar extinction at 450 mμ was estimated in oxidized and reduced xanthine oxidase. This figure correlates with the contribution from the FAD<sup>21</sup>; it is known that free FAD and bound FAD have essentially the same absorbancy at 450 mμ (ref. 22). The suggestion<sup>23</sup> that the visible absorption spectrum of xanthine oxidase is due to molybdenum appears to be incorrect. We have confirmed the findings of Rajagopalan and Handler<sup>19</sup> using our more highly purified xanthine oxidase preparation and have compared the absorbances with those from spinach ferredoxin (Table 3). It can be seen (comparing columns 2 and 5) that the values for xanthine oxidase are four times those for spinach ferredoxin. The same result is obtained when the molar optical rotatory dispersions of these two materials are compared (Table 3).

It is possible that the iron atoms in the plant ferredoxin chromophore are in a mixed spin state under physiological conditions. If this were so, small changes in temperature would radically alter the observed spectral properties. We have therefore measured the circular dichroism of spinach ferredoxin over the temperature range 0°–30° C (Fig. 3). As was found previously in rubredoxin<sup>11</sup> the overall shape of the spectrum remains unchanged and it would seem likely that the slight reduction in intensity on raising the temperature resulted from thermal broadening of the vibronic absorption bands. Thus it can be concluded that mixed spin states are not involved over the physiological range of temperature though the possibility remains open whether they occur at lower temperatures<sup>24</sup>.

Further insight into the environment of the iron chromophore may be obtained by altering the conformation of the protein. We have investigated this possibility by measuring the spectra of spinach ferredoxin in 8 molar urea (Fig. 1) and as a function of time at pH 11 in sodium hydroxide-sodium carbonate buffer (Fig. 4). Similar experiments were carried out with xanthine oxidase solutions in buffer containing 9 molar urea and also in solutions saturated with urea at room temperature.

Although dissolving the ferredoxin in 8 molar urea has only a slight effect on the absorption spectrum, the circular dichroism is much changed. The original spectrum is replaced by one with very different and much weaker absorption bands. The effect of urea is presumably to alter the helical nature of the protein around the non-haem iron chromophore. The results indicate that urea treatment leads to a chromophore which is in a centre of lower asymmetry due to loss of helical structure. The circular dichroism at 635 mμ in the protein treated with urea probably results from an iron-sulphur band<sup>25</sup>.

At pH 11 the protein is attacked by hydroxyl ions hydrolysing the amide linkages; this treatment will, of course, affect the more exposed portions of the molecule initially. Again it is evident that the optical activity observed for the iron chromophores arises largely from the conformation dictated by the protein structure. Thus

after about 45 min the circular dichroism has fallen by more than half, but the effect on the absorption spectrum is only slight. Further reaction causes a steady loss of absorption between 300 and 600 m $\mu$  together with loss of optical activity. The circular dichroism curves do not, however, pass through common points (isodichroic points) on the base line, indicating that, although the original optically active chromophore is disappearing, a new one is being formed. In particular, a new Cotton effect appears at about 640 m $\mu$ , associated with the shoulder at 650 m $\mu$  in the absorption spectrum (this region of the absorption spectrum is only slightly affected by the treatment with alkali). This band is at the same wavelength as the band obtained with 8 molar urea. The effect of treatment at pH 11 is probably to produce the same effect as urea, that is to destroy the helicity of the protein in the neighbourhood of the iron chromophore leaving small Cotton effects as a result of isolated iron-sulphur chromophore.

With xanthine oxidase there was no change in the absorption, circular dichroism or optical rotatory dispersion spectra when these were measured immediately in 9 molar urea, but after 30 h at 0° C the circular dichroism had decreased by 21 per cent while there was a 24 per cent loss in absorption at 450 m $\mu$ . These findings probably indicate that iron and flavin have been lost from the enzyme as reported previously from studies in 4 molar urea<sup>19</sup>. Using a room temperature saturated urea solution (20 molar) denaturation occurred rapidly; all characteristic optical activity above 300 m $\mu$  was lost, and the fully denatured protein showed a 74 per cent loss in absorption at 450 m $\mu$  after about 6 h. In no case was a change comparable with that found with spinach ferredoxin observed. It has been previously noted<sup>26</sup> that at low concentrations urea tends to act as a competitive inhibitor for xanthine rather than to cause conformational changes in the protein. The differences in the effect of urea on xanthine oxidase and spinach ferredoxin are presumably a reflexion of the great difference in the protein structures and sizes of these proteins.

We have also measured the spectra of parsley ferredoxin. These are shown in Fig. 5. The results have been calculated using a molecular weight of 13,000 as with spinach ferredoxin (Bendall, Gregory and Hill<sup>27</sup> give the molecular weight as 12,200 from ultracentrifuge measurement and 14,000–19,000 as the minimum molecular weight from amino-acid analysis. We have used here the same value for the molecular weight as in spinach ferredoxin (13,000)). The spectra are very similar both in intensity and shape

to those of spinach ferredoxin. The visible and near ultra-violet spectra in these proteins arise therefore from almost identical chromophores.

A previously reported optical rotatory dispersion curve<sup>10</sup> referred to a sample of parsley ferredoxin which contained some colourless (probably poly-phenolic) impurity. A similar impurity is often present in spinach ferredoxin, which has a strong absorption band at 265 m $\mu$ , a strong positive circular dichroism at 265 m $\mu$  and a much weaker negative circular dichroism at 295 m $\mu$ . The presence of this impurity does not affect the results of circular dichroism above 320 m $\mu$  but introduces a plain positive optical rotatory dispersion curve into the visible region.

The optical properties of the reduced proteins are given for spinach ferredoxin (Fig. 1) and xanthine oxidase (Fig. 2). Measurements from these spectra are given in Table 2 together with those for other non-haem iron proteins. The spectra of dithionite-reduced spinach ferredoxin and xanthine oxidase are very similar above 300 m $\mu$ . The only difference is the change in sign of the long wavelength band, a similar effect to that seen in the oxidized spectra. The negative band at 580 m $\mu$  in reduced xanthine oxidase cannot arise from a reduced "ferredoxin-like" chromophore and the differences at long wavelength for both oxidized and reduced xanthine oxidase may arise from an electronic transition involving molybdenum. This conclusion is supported by the parallel electron spin resonance study which failed to reveal any flavin semiquinone—a component which might have been expected to contribute to the absorption spectrum of the reduced xanthine oxidase in this region. The electron spin resonance signals found for molybdenum and non-haem iron in the present samples of xanthine oxidase were identical to those reported previously (ref. 12 and Bray, R. C., and Knowles, P. F., unpublished) under each of the reduction conditions examined.

The absorption spectra of xanthine- and dithionite-reduced xanthine oxidase were compared after both the circular dichroism and optical rotatory dispersion experiments. Several workers<sup>28–30</sup> have reported that the extent of rapid reduction of the enzyme with xanthine does not exceed 50–60 per cent of the value obtained with dithionite. No attempt was made in the present investigation to follow the rapid phase of reduction; the results obtained refer to reactions lasting about 45 min. It was found that the extent of reduction produced by xanthine was 60–65 per cent of that produced by dithionite. The extent of reduction calculated from the circular dichroism and optical rotatory dispersion spectra agreed well with that obtained from the absorption spectra of the same solution. There was no indication of further slow changes in the spectra as reported by Bray *et al.*<sup>13</sup>, possibly because the present studies were made with a substantially more highly purified enzyme.

These results suggest that xanthine only partially reduces the iron chromophores. This is confirmed by the observation that the circular dichroism and optical rotatory dispersion curves for the oxidized and reduced species all pass through the same points, isodichroic points being seen at 502 m $\mu$ , 405 m $\mu$  and 352 m $\mu$  and isorotatory points at 432 m $\mu$ , 377 m $\mu$  and 333 m $\mu$ . In addition, on re-admitting air to the cells, spectra were obtained which passed through the same isospectral points. The observation of these points (analogous to isosbestic points) can only be interpreted as indicating the presence of just two species of iron, the oxidized and the reduced. It should, however, be pointed out that from electron spin resonance studies<sup>12</sup> it is known that the molybdenum species present in xanthine- and dithionite-reduced xanthine oxidase are quite different.

The molybdenum of methanol-inactivated xanthine oxidase has been shown<sup>12,17</sup> by electron spin resonance to be in the pentavalent state with a less than axially symmetrical environment. The valency of molybdenum in the oxidized enzyme is probably six<sup>20</sup>. A difference might

Fig. 5. The optical properties of parsley ferredoxin. Absorption (—), and optical rotatory dispersion (— · — · —), of the oxidized protein. Also absorption (with dithionite) (---) and optical rotatory dispersion (·····) of the reduced protein.

be expected between the optical properties of active and of methanol-inactivated xanthine oxidase due to the change from  $\text{Mo}^{\text{VI}}$  to  $\text{Mo}^{\text{V}}$ . The absorption, circular dichroism and optical rotatory dispersion spectra obtained for oxidized- and dithionite-reduced methanol-inactivated xanthine oxidase were found to be identical with those of the active enzyme. This again indicates that the contribution to the spectra from molybdenum is small and is masked by the "ferredoxin-like" chromophores. Until more evidence is available, the assignment of the band at 580 m $\mu$  to molybdenum must remain tentative.

The study of the position and magnitude of optically active absorption bands gives a very delicate indication of molecular environment. Those observed for plant ferredoxin and xanthine oxidase are very similar not only in position but also in the relative magnitude per iron atom and must therefore arise from virtually identical non-haem iron chromophores. A comparison of the magnitudes per protein molecule indicates that xanthine oxidase probably contains four identical pairs of non-haem iron atoms while spinach ferredoxin contains one such pair. This confirms an earlier report based only on optical rotatory dispersion measurements<sup>31</sup>. Our results also suggest that xanthine only effects partial reduction of the iron relative to dithionite.

These findings correlate with the findings of electron spin resonance studies (Gibson, J. F., and Bray, R. C., unpublished) and with Mössbauer studies<sup>32</sup>. The latter indicate that at pH 6.0, dithionite reduction affects all the iron atoms while reduction with salicylaldehyde affects only up to 20 per cent of the iron present. A model to explain all these experimental observations, which involves spin-paired iron atoms, has been proposed by Gibson *et al.*<sup>33</sup>. This is a refinement of an earlier model by Brintzinger, Palmer and Sands<sup>34</sup>. A low spin ferrous atom interacting with a radical<sup>35</sup>, however, cannot be ruled out as a possibility from the available data, though the transfer of only one electron during the catalytic cycle of spinach ferredoxin would favour the two iron atom model.

The presence in xanthine oxidase of four pairs of iron atoms, two atoms of molybdenum and two molecules of FAD, would require ten electrons to be fully reduced which agrees well with the figure estimated by Ehrenberg and Bray<sup>9</sup>. This two iron-two sulphur chromophore has been found in material of plant and mammalian origin; it may therefore be expected as a common unit in nature and to occur in many enzymes with redox function. There is already good evidence for the chemical similarity of non-haem iron proteins from mammalian, plant and bacterial sources<sup>2,19,36-43</sup>. There must be large differences in protein structure, however, to account for the facts that although the optical rotatory dispersion spectra of spinach ferredoxin and adrenodoxin<sup>36</sup> are virtually identical, the electrode potentials differ widely ( $-432$  and  $+164$  mV respectively).

The bacterial ferredoxins<sup>2,5-7,15,44</sup> have been found to substitute for spinach ferredoxin in cell extracts and have a similar function, namely electron transport. It should be emphasized that this interchangeability is probably due to their similar redox potentials and not to similarity in structure<sup>45</sup>. They do in fact differ greatly in their spectroscopic properties. Not only do the wavelengths of the optically active absorption bands differ, but the whole character of the Cotton effects changes. Bacterial ferredoxin has a relatively simple circular dichroism spectrum<sup>10,11</sup> with only about one-tenth of the intensity of plant ferredoxin although it contains about six atoms of iron. These results can be compared with those of spinach ferredoxin and xanthine oxidase in Tables 1 and 2. Furthermore, treatment with 8 molar urea causes only a slight change in the optical activity<sup>19</sup> of bacterial ferredoxin, showing that protein conformational changes do not affect the chromophore. The small intensity of the circular dichroism also indicates that the environment of the chromophore here is in a site of low helicity; it is

significant that the circular dichroism of spinach ferredoxin in 8 molar urea is of the same order of magnitude as that of untreated bacterial ferredoxin. The reactivities of the ferredoxins (plant or bacterial) with the chelating agents 2,2'-dipyridyl and 1:10-*ortho*-phenanthroline are also different. In bacterial ferredoxin loss of iron from the protein is more rapid from the oxidized species than from the reduced species<sup>46</sup>, the reverse being true with spinach ferredoxin (Garbett, K., and Stangroom, J. E., unpublished). The iron chromophores in bacterial ferredoxin are evidently of a totally different nature from those reported in this work.

We thank Dr R. C. Bray and Dr L. I. Hart for helpful discussions. Work at the Chester Beatty Research Institute was supported by grants from the MRC, the British Empire Cancer Campaign for Research and by a grant from the National Cancer Institute, US Public Health Service.

# Absence of an Oxygen Effect and the Genetically Determined Repair Processes

by

D. ROY DAVIES

Wantage Research Laboratory (AERE),  
Berkshire

Certain mutants are more sensitive to  $\gamma$ -irradiation in the absence of oxygen than in its presence. This unusual effect is controlled by one gene.

It is generally observed that cells exposed to sparsely ionizing radiations in the presence of oxygen suffer more damage than if exposed in its absence. The extent of the enhancement varies according to the organism and strain tested, environmental conditions and the criterion of damage<sup>1</sup>. Two systems which do not behave in this way are bacteriophage and transforming principle, which exhibit similar radiosensitivity in the presence and absence of oxygen<sup>2,3</sup> when irradiated extracellularly. Another aspect of the oxygen effect was recently reported by Alper<sup>4</sup>, who observed that not only were ultra-violet sensitive bacterial mutants frequently more sensitive to ionizing radiations, but also that they had a smaller oxygen enhancement ratio (OER) than their parental strains. We have recently isolated several mutant strains of the unicellular green alga, *Chlamydomonas reinhardtii*, which are highly sensitive to ultra-violet light and the enhanced sensitivity of which is probably caused by a defective capacity for repairing damage. Some of these mutants have an unchanged response to ionizing radiation, others are more sensitive, whereas still others are more sensitive than the parental form only when irradiated in the absence of oxygen. In the present communication the response to  $\gamma$ -radiation of one of this last class of mutants is described.

Synchronous populations of haploid cells of the parental wild type (WT) and of one of the ultra-violet sensitive (UVS 1) forms (both of mating type +) were grown in liquid cultures using a standard medium<sup>5</sup>. To ensure absolute uniformity of developmental stage in all experiments, the cells were denitrified to convert them into gametes<sup>6</sup>, although all available evidence indicates that the vegetative and gametic stages have similar sensitivities. Diploid stages were used for some of the experiments and these were produced by mating gametes of + and - mating type, using techniques described elsewhere<sup>7</sup>. In all instances assays of viability after irradiation were made by plating cells at suitable dilutions on a yeast acetate supplemented medium in 1.5 per cent agar, and the criterion of survival was the production of a colony of 100 cells from a single cell. Cultures were maintained in an incubator at 25°C and 500 ft.-candles light intensity. A 4,000 c. cobalt-60 'Hotspot', which gave a dose rate of 14,900 rads/min, was the source of  $\gamma$ -radiation. Samples were exposed in liquid minimal medium and vigorously bubbled with oxygen or nitrogen (<10 p.p.m. oxygen) during irradiation and for 15 min before. Hersch cell measurements showed that the level of oxygen in the samples bubbled with nitrogen for this period of time was less than 130 p.p.m. It is necessary to irradiate a photosynthesizing system such as *Chlamydomonas* in the dark to ensure that there is no intracellular generation of oxygen.

The response of haploid WT and UVS 1 cells irradiated in oxygen or nitrogen is shown in Fig. 1. The WT cells have an OER of 2.8. UVS 1 cells irradiated at the same time and under identical conditions have a similar response to that of WT when irradiated in the presence of oxygen, but are more sensitive than WT when irradiated under

anoxic conditions. In nitrogen there is an apparently exponential decrease in survival of UVS 1 cells with increasing dose, at least for survival down to  $10^{-3}$ , and superficially oxygen appears not to be dose modifying—a feature noted also by Alper<sup>4</sup> in one of the bacterial mutants sensitive to ultra-violet light. Closer examination, however, indicates that the dose response curve in nitrogen could be a composite one, one part—representing the majority of the population (about 90 per cent)—which is more sensitive in nitrogen than in oxygen, and the remaining 10 per cent which has a normal OER. The response of this latter 10 per cent in nitrogen, if normalized to a 100 per cent survival value, is identical with that of the WT. Proof of the heterogeneous nature of this UVS 1 haploid population has been obtained by the isolation of two distinct types of cell population. One is identical to UVS 1 in having the composite response in nitrogen as shown in Fig. 1. The other, termed sub-population UVS 1/B, has a response to  $\gamma$ -radiation in nitrogen similar to that of the WT (as in Fig. 1), that is, it has a normal OER. There must, of course, then be another sub-population UVS 1/A, representing 90 per cent of the UVS 1 population, which is more sensitive in nitrogen than in oxygen, but we have been unable to isolate this UVS 1/A form uncontaminated from the B sub-population. The nature and origin of these sub-populations will be discussed later, and the reason for this inability to isolate pure UVS 1/A will then become apparent.

Fig. 1. The response of haploid cells of WT (○) and UVS 1 (△) to  $\gamma$ -radiation. Closed symbols, irradiation in oxygen; open symbols, in nitrogen.

Fig. 2. The response of haploid cells of WT ( $\circ$ ) and UVS 1 ( $\Delta$ ) to  $\gamma$ -radiation, in the presence of  $10^{-2}$  molar cysteamine. Closed symbols, irradiation in oxygen; open symbols, in nitrogen. Broken lines indicate the responses obtained in the absence of cysteamine (see Fig. 1).

Though the *B* sub-population has a normal OER like the WT, it is not WT in its response to UV, but remains as sensitive as UVS 1. Furthermore, *B* cells are distinguishable from WT by their less vigorous growth after irradiation with high doses in nitrogen; in other words, the *B* change may not involve a full restoration of the wild type phenotype for resistance to  $\gamma$ -radiation in nitrogen.

An apparent reversal of the oxygen effect has been shown to be caused by the production of toxic cuprous ions under anoxic conditions<sup>8</sup>. Because the minimal medium used in the present experiments had trace quantities of copper salts, a test was made of their role in determining the response of UVS 1 to  $\gamma$ -radiation. Haploid cells were thoroughly washed, and then irradiated in buffer free of copper. The results obtained were similar to those shown in Fig. 1, indicating that copper toxicity was not responsible for the enhanced sensitivity of UVS 1 when irradiated in nitrogen<sup>8</sup>.

To further characterize the difference in the response of UVS 1 and WT cells, haploid strains of both genotypes were exposed to  $\gamma$ -radiation under oxic and anoxic conditions in the presence of  $10^{-2}$  molar cysteamine. Freshly prepared solutions of cysteamine were used and the pre-treatment with nitrogen was as previously described. In the case of the oxic irradiations, solutions were bubbled with oxygen for only 3 min before irradiation to reduce oxidation of the cysteamine. As the data in Fig. 2 show, this protective compound was effective for both genotypes under both gas conditions, but particularly so for UVS 1 under anoxic conditions. This contrasts with the greater protection usually observed in cellular systems following irradiation in oxygen, but agrees with the results obtained for bacteriophages<sup>9</sup>. A particularly significant feature of these results was that cysteamine completely eliminated the characteristic heterogeneity of the haploid UVS 1 population following irradiation in nitrogen and raised the level of survival of both sub-populations to that observed in the WT. Cysteamine thus corrected the genetic defect in UVS 1 and allowed a better survival after irradiation in nitrogen than in oxygen.

When homozygous diploid spores of UVS 1 and of WT were irradiated at the "2 h stage"<sup>10</sup> in either oxygen or

\* I am grateful to Miss T. Alper for suggesting this experiment.

nitrogen the survival curves shown in Fig. 3 were obtained. In contrast to the haploid cells, diploid UVS 1 cells were more sensitive than WT in the presence of oxygen. Whereas the WT cells had an OER of 2.4, anoxia conferred no protection on the UVS 1 cells—in fact the latter were consistently more sensitive in nitrogen than in oxygen. Furthermore, in contrast to the haploids, the whole of the UVS 1 population, when in the diploid state, was homogeneous in this respect—that is, *A* and *B* could not be distinguished. To confirm the observation that the two sub-populations, *A* and *B*, of UVS 1 did not differ in their response when in the diploid state, diploid homo-

Fig. 3. The response of diploid cells of WT ( $\circ$ ) and UVS 1 ( $\Delta$ ) to  $\gamma$ -radiation. Closed symbols, irradiation in oxygen; open symbols, in nitrogen.

Fig. 4. The response of diploid cells of UVS 1/*B* to  $\gamma$ -irradiation in the presence of oxygen ( $\blacktriangle$ ) and of nitrogen ( $\triangle$ ).

zygous UVS 1/B cells were irradiated. When these cells were irradiated in oxygen or nitrogen those in nitrogen were more sensitive to radiation (Fig. 4). Thus whereas haploid UVS 1/B cells show a normal OER, diploid UVS 1/B cells like haploid and diploid UVS 1 cells are more sensitive in nitrogen than in oxygen. There is, of course, no *a priori* reason why haploid and diploid cells should behave in a similar manner. The initial lesions induced by radiation in the two forms may well be identical but subsequent steps in the development of the lesion and the critical lethal event may be different.

### Mutational Changes

The two changes we are concerned with are the nature of the mutational change involved in the induction of the UVS 1 strain from the WT, and that involved in the origin, during vegetative reproduction, of the UVS 1/B population.

The isolation of the UVS 1 mutant after nitrosoguanidine treatment will be described elsewhere. The genetic nature of the change involved was analysed by crossing it with the WT parental strain. Diploid spores were WT in their response to  $\gamma$ -radiation, and the characteristic UVS 1 sensitivity to  $\gamma$ -radiation in nitrogen thus behaves as a recessive character. Tetrad analysis (twenty-three tetrads) of the spores gave a 1:1 segregation among the haploid progeny for the UVS 1 versus WT response. Furthermore, all the former were sensitive to ultra-violet light and the latter resistant. Tests of another fifty single cell isolates from this cross, which showed the UVS 1 response to  $\gamma$ -radiation, showed that all were also sensitive to ultra-violet light. Thus the absence of an oxygen effect in UVS 1 cells is due to a nuclear factor which is controlled by a single gene, and the response to ultra-violet light is controlled by the same or by a closely linked gene.

The problem of the origin of the UVS 1/B population is a much more difficult one. If single cells of UVS 1 are isolated, and each allowed to form a new population, approximately 90 per cent of these populations are heterogeneous, and two sub-populations UVS 1 and UVS 1/B can be isolated from each one (see Fig. 5). Thus during vegetative reproduction UVS 1/A cells are continually giving rise to UVS 1/B cells. To determine whether the reverse change occurs from B to A one hundred single cells were isolated from a B population and allowed to multiply; the hundred populations were then tested for their response to  $\gamma$ -radiation in nitrogen. All had a normal OER, that is, no type A had been produced. B populations have been maintained by vegetative propagation for several months and the change from A to B is therefore heritable and stable.

A more detailed analysis of the UVS 1/A to UVS 1/B change was precluded by the fact that when UVS 1/B strains were crossed with any strain other than UVS 1/B, a high proportion of the diploid zygospores gave rise to aberrant haploid progeny. Meiosis appeared to be completed normally, but later growth and division of the haploid products was extremely slow and aberrant. In

the limited number of normal tetrads (thirty) obtained when UVS 1/B (as + or - parent) was crossed with UVS 1, all progeny had the UVS 1/B response to  $\gamma$ -radiation. This suggests an extrachromosomal control—possibly UVS 1/B has a cytoplasmic suppressor<sup>13</sup> for part of the UVS 1 gene, though some form of chromosomally based instability cannot be ruled out.

The mutant form UVS 1, selected on the basis of its high sensitivity to ultra-violet light, represents the first known example of an actively metabolizing cellular system which is more sensitive to a sparsely ionizing radiation when irradiated in the absence than in the presence of oxygen. Whatever interpretation is put on this observation it must be reconciled with the fact that the parental strain from which UVS 1 was derived, when irradiated at the same time and under identical conditions, showed a normal oxygen effect. It seems unlikely that there is an inherent difference in sensitivity between UVS 1 and WT; if this were the case differences in the response to oxygen would also be expected, and this did not occur in the haploids. Alper<sup>4</sup> has pointed out that in some bacteria the repair system which deals with ultra-violet photo-products also deals with a certain part of the damage induced by ionizing radiation. She observed that forms of bacteria sensitive to ultra-violet light had a lower OER when exposed to sparsely ionizing radiation than did the more ultra-violet resistant parental forms, and has interpreted these results on the basis of the induction and differential repair of two types of damage—N and O. The former has a low, and the latter a high, OER. Because the increased sensitivity of bacterial mutants is caused by an inability to repair N type damage, the end result of the greater importance of this class of damage is the lower OER. This interpretation of the situation, however, cannot apply to the *Chlamydomonas* data, for if there were two similar classes of lesions induced in this species, then the contribution of N type to the total damage in UVS 1 would have to be large to be capable of swamping the O type. The presence of these extra N type lesions in UVS 1 would necessarily give rise to an enhanced sensitivity of cells irradiated in oxygen, unless an increase in N (caused by a lack of repair) was accompanied by a concomitant decrease in O, which is unlikely. Although such an enhanced sensitivity in oxygen did occur in the diploid, it did not occur in the haploid.

A possible interpretation of our data is as follows: after the initial absorption of energy, different reactions occur with the radicals in the target molecule, or possibly in its environment, in the presence and in the absence of oxygen. Although many of the lesions induced as a result of the reactions in these two gas conditions will be identical in kind, there will be quantitative as well as qualitative differences. In UVS 1 a system concerned with the recognition and repair of some of the particular lesions induced under anoxic conditions is defective, and the survival level, as a consequence, remains low. This concept can be accommodated within a framework such as that developed by Alexander<sup>11</sup> and Howard-Flanders<sup>9</sup>. This proposes that a radical induced in the target molecule

Fig. 5.

(presumably DNA) can undergo one of three reactions—interaction with oxygen, interaction with another radical, or hydrogen donation to restore the original configuration; in the presence of oxygen the first predominates. In the present interpretation it is assumed that the lesions resulting from the peroxy-radicals formed in oxygen as well as some of those resulting from the formation of other radicals in nitrogen may be repairable by one system. In the absence of oxygen, other reactions, possibly radical-radical interaction leading to cross-linking, may occur, and these lesions are repairable by a second system. This repair system, which also deals with certain ultra-violet photoproducts, could be defective in UVS 1. The third reaction—hydrogen donation—may be important in interpreting the results obtained with cysteamine. Several theories have been proposed to account for the protective activity of this compound, but any interpretation of its action in the present system has to be reconciled with the observation of a greater protection in UVS 1 than in WT and in anoxic rather than oxic conditions. If the "radical scavenger" hypothesis is accepted it is difficult to understand why UVS 1 and WT should differ, whereas the "induced anoxia" theory is clearly invalid; the "mixed disulphide" hypothesis could in theory be reconciled with a protection of a radiosensitive repair enzyme in UVS 1. The last model of cysteamine action involves its activity as a hydrogen donor, and there is good evidence to support this model for some systems in which the target molecule is clearly DNA<sup>12</sup>. If this is the mechanism involved in the *Chlamydomonas* experiments then the absence in UVS 1 of that particular repair system which copes with some part of the anoxic damage can be masked by the restoration of damage which follows hydrogen donation from cysteamine in the absence of oxygen.

The nature of the relationship demonstrated genetically in the present experiments, between the repair of certain

ultra-violet photoproducts and of lesions induced by ionizing radiations in anoxic conditions, has yet to be elucidated at the biochemical level.

If the interpretation of differential repair systems acting on some part of the damage induced under oxic and under anoxic conditions is shown to be correct, then this concept will be significant in a re-evaluation of certain radiobiological observations and also possibly ultimately in radiotherapy. It is a general problem in radiotherapy that tumour foci can be relatively anoxic and thus more resistant to sparsely ionizing radiations than the better oxygenated surrounding tissues. Compounds which inhibit the repair of ultra-violet photoproducts are well known; if similar compounds can be found which block the systems responsible for the repair of anoxic damage, that is, which simulate the genetic block in UVS 1, then this could be a means of enhancing damage in the tumour cells while leaving the response of surrounding tissues unchanged.

I thank Mrs V. Bronsdon and Mr J. Harrison for their valuable technical assistance.

## Plasmodial Fusion and Lethal Interaction between Strains in a Myxomycete

by  
M. J. CARLILE  
JENNIFER DEE

Department of Biochemistry,

University of London,  
and Department of Genetics,  
University of Leicester

After plasmodial fusion between certain strains of *Physarum polycephalum* there is a lethal reaction which may end in the total destruction of one or both plasmodia.

THIS is a preliminary account of a study of fusion between plasmodia of the Myxomycete *Physarum polycephalum* Schweinitz and of a lethal reaction which follows some fusions. The plasmodium of *P. polycephalum* is a motile mass of protoplasm of variable form without a rigid wall and not sub-divided into cells (that is, coenocytic). Vigorous protoplasmic streaming takes place continuously through a network of channels ("veins") at rates as great as 1 mm/sec with reversals of flow approximately once/min<sup>1,2</sup>. The nuclei divide synchronously even in a large plasmodium which may cover an area of many square centimetres<sup>3</sup>.

The plasmodial phase, which alternates in the life cycle with a haploid amoeboid phase, is initiated by a sexual process, the fusion of two amoebae (myxamoebae). One of us (J. D.) has shown that the two amoebae must differ in mating type, and that the mating types, of which four have been identified, are determined by a series of alleles at a single locus<sup>4</sup>. In appropriate conditions the plasmodium produces uninucleate spores, from which haploid uninucleate amoebae emerge. Nuclear fusion certainly takes

place before sporulation, because spore formation is accompanied by meiosis<sup>5</sup> and recombination of genetic markers<sup>6</sup>.

The strains of *P. polycephalum* used in our investigations were all derived from a plasmodium supplied to one of us (J. D.) by Professor H. P. Rusch of Wisconsin University in 1957. Clones of amoebae were maintained in two-membered culture with *Escherichia coli*. Plasmodia were obtained by mixing clones of amoebae of differing mating type. Details of the method by which clones were obtained, cultured and mated have been published previously<sup>4,6</sup>. Plasmodia were freed from *E. coli* by migration on acidified plain agar, pH 4.6, sometimes with the addition of streptomycin. They were then maintained in pure culture on a semi-defined agar medium containing glucose, peptone, mineral salts, vitamins and haematin, closely resembling that advocated by Daniel and Baldwin<sup>7</sup>. The interaction between two plasmodial strains was examined by inoculating the strains on opposite sides of a Petri dish containing semi-defined agar medium and observing the response when, after 2–3 days of growth, the plasmodia met at the centre of the dish.

Fig. 1. Fusion between plasmodia of the same strain showing appearance (a) about one hour and (b) several hours after contact. ( $\times 2.8$ .)

### Plasmodial Fusion

When the advancing margins of two plasmodia of the same strain meet they rapidly fuse. Within a few minutes of contact movement of protoplasm between the plasmodia can be detected, and within about 1 h prominent "veins", visible to the naked eye, link the two plasmodia (Fig. 1a). By this time the plasmodia usually will have merged completely over an extensive front, and within a few hours it is no longer evident that the resulting plasmodium originated from two separate plasmodia (Fig. 1b). When plasmodia of different strains are tested for fusion with each other in various combinations of two at a time, some pairs of plasmodia consistently fuse with each other and other pairs consistently fail to fuse (Fig. 2a). These latter plasmodia may remain in contact for days without fusing, although after a few hours one plasmodium may grow over the other making observation difficult (Fig. 2b). Thus whether plasmodial fusion occurs depends in the first instance on which strains are paired rather than on their physiological state, a conclusion reached by Gray on the basis of less extensive data<sup>8</sup>.

In order to investigate the factors involved in determining plasmodial fusion, we have carried out a series of experiments in which groups of plasmodia derived from closely related clones of amoebae have been tested for fusion with each other in all combinations of two at a time. Because of the known relationships among the plasmodia, we were able to make definite predictions of the results expected on the basis of various inherited compatibility systems. For one related set of plasmodia, all descended from the two clones of amoebae previously designated<sup>6</sup> *a* and *i*, we found that a scheme based on one pair of gene alleles ( $f^1$  and  $f^2$ ) was sufficient to account for all the results. On this scheme, fusion occurs only between plasmodia with identical genotype at the *f* locus. The plasmodia are diploid (or dikaryotic) and so each carries two alleles at each gene locus (Table 1). In similar tests with other groups of plasmodia derived from more dis-

+, Denotes fusion; -, denotes failure to fuse.

tantly related clones of amoebae, the results are more complex and suggest the presence of other loci influencing plasmodial fusion. We are still analysing these, and results will be published in detail elsewhere. We have so far found no evidence that the mating type locus (*mt*) influences plasmodial fusion. In this respect, our results differ from those of Collins<sup>9,10</sup>, who has studied plasmodial fusion in the Myxomycete *Didymium iridis* and has tentatively concluded that it is controlled in this species by four loci, including the mating type locus.

### The Lethal Interaction

As indicated here, pairing plasmodia which are of different strains but of identical genotype with respect to the fusion locus (*f*) results in apparently normal fusion. Within about 1 h prominent "veins" connect the two plasmodia. With some combinations of strains the final result of fusion is a single plasmodium of which the origin from separate plasmodia is no longer evident, as with the fusion of plasmodia of the same strain. With other combinations of strains, however, fusion may be followed by a destructive reaction which varies considerably in severity. The first indication of the reaction, occurring after about an hour, is a cessation of streaming in "veins" at and near the region where fusion occurred. Gelling of protoplasm probably takes place, as Brownian movement of particles in the protoplasm ceases, and changes in colour and appearance make the affected area obvious

Fig. 2. Failure of fusion between plasmodia of different strains showing appearance (a) about one hour and (b) several hours after contact. ( $\times 3.5$ .)

to the naked eye. The area affected may remain restricted, or may spread to occupy much of one or both interacting plasmodia. In extreme instances total destruction of one or both of the plasmodia occurs, no further growth takes place, and attempts to sub-culture demonstrate the absence of viable material. When, as is usual, some of the plasmodium survives, the affected area becomes sharply delimited and is subsequently invaded and digested by plasmodia from the surviving regions. Lethal interaction between strains has not been seen in the absence of plasmodial fusion. Although the phenomenon clearly has a genetic basis, in that some combinations of strains have never been observed to result in a lethal interaction, whereas some consistently do, genetic analysis of the phenomenon has not yet been attempted. It is also unknown whether the surviving regions are genetically identical with either of the interacting plasmodia.

We are unaware of any previous report of a lethal reaction after plasmodial fusion in Myxomycetes. A lethal interaction after vegetative fusion has, however, been reported in the filamentous fungus, *Neurospora crassa*, where heterocaryons are successfully established only between strains identical at certain loci. When hyphae from strains not identical at the appropriate loci meet, normal fusion occurs, but death of the cells immediately adjacent to the fusion follows<sup>11</sup>. The sequence of events described and figured is similar to what we have observed in *Physarum*. The reaction in the Myxomycete is, however, far more spectacular, because many square centimetres instead of two adjacent cells are involved. The greater extent of the reaction in the Myxomycete is probably the result of efficient mixing of protoplasm from the interacting plasmodia resulting from the very rapid protoplasmic streaming. In *Neurospora*, studies involving micro-injection strongly suggested that the material that brought about death through transfer between the genetically unlike cells was a soluble cytoplasmic protein<sup>12</sup>.

In *P. polycephalum*, the process of cell fusion is apparently controlled by one gene locus (*mt*) when it occurs in amoebae and by another gene locus (*f*) when it occurs in plasmodia, the *mt* locus being without effect on plasmodial fusion and the *f* locus without effect on the fusion of amoebae. Thus each of these two genes seems to have expression in only one of the two phases of the life cycle. It is of interest that another gene (*act*), which confers actidione resistance on the amoebae, also appears to influence only one phase of the life cycle and to lack similar expression in plasmodia<sup>6</sup>. As well as acting at

different stages in the life cycle, the *mt* and *f* genes differ in their mode of action; amoeboid (sexual) fusion occurs only between amoebae differing in *mt* genotype, whereas plasmodial (vegetative) fusion occurs only between plasmodia identical at their *f* loci. The discovery of lethal interactions following plasmodial fusion indicates that for plasmodial fusion to proceed to completion, even closer genetical identity is required.

The mating system controlling sexual fusion in *P. polycephalum* is similar to systems promoting outbreeding and leading to genetic recombination in a wide variety of other organisms. There are few studies in other organisms on the genetic control of vegetative fusions, that is fusions regarded as not directly related to sexual reproduction. In the Fungi<sup>13</sup> vegetative fusion resulting in the establishment of a heterocaryon seems often to be limited to material that is genetically closely similar, either through a genetic system which prevents fusion or through a lethal interaction following protoplasmic mixing. In mammalian cells in tissue culture, however, fusion between cells of widely different genotype (for example, those of mouse and man<sup>14</sup>) can occur and result in viable heterocaryons, a situation wholly different from that found in the Fungi and in *P. polycephalum*. Our present results suggest that the latter organism constitutes particularly favourable materials for the study of such genetically restricted vegetative fusions.

We thank Professor E. B. Chain for helpful discussion and Mr G. D. Gilder for technical assistance. This work is being continued as part of a broad programme of research on myxomycetes now being undertaken at the Department of Biochemistry, Imperial College, and at the Department of Genetics, University of Leicester.

## Relationship between Thymus and Hypophysis

by  
W. PIERPAOLI\*  
E. SORKIN

Schweizerisches Forschungsinstitut,  
Medizinische Abteilung,  
Davos-Platz, Switzerland

Young adult mice injected with anti-hypophysis serum develop wasting disease such as after neonatal thymectomy and atrophy of the thymus. This and the finding of changes in the hypophysis after neonatal thymectomy suggest a relationship between the function of the hypophysis and that of the thymus.

THE thymus plays a dominant part in the development of immunological function<sup>1-3</sup>. Impaired antibody synthesis, failure to develop cell mediated immunity and wasting disease result from thymectomy shortly after birth<sup>4,5</sup>. The wasting syndrome, which is characterized by a rapid weight loss and death of the animals, begins to manifest itself only several weeks after neonatal thymectomy and at a stage of development when the animals

seem to be normally healthy. Contradictory views exist as to the mechanism responsible for the wasting disease<sup>6-12</sup>. It has also been suggested that the thymus plays a part in body growth and development (see, for example, ref. 13).

There is an important relationship between the thymus and several endocrine glands<sup>14-18</sup>. The anterior pituitary gland deserves special mention because growth hormone causes a marked enlargement of the thymus<sup>18</sup>. In an

\* Research fellow of the Italian National Research Council, Rome.

attempt to analyse the relationship between the thymus and the pituitary two main types of experiments were performed. In the first experiments, young adult mice were injected with rabbit anti-mouse hypophysis serum. In the second experiments, newborn mice were thymectomized and their hypophysis examined histologically at various times after thymectomy. It was noted that anti-hypophysis serum produced loss of weight, wasting disease and thymus involution or even complete disappearance of the thymus. Neonatal thymectomy, on the other hand, resulted in definite morphological changes in the hypophysis.

**Mice treated with anti-hypophysis serum.** Inbred C57/BL and outbred NMRI male mice, 25–35 days old, ranging in weight from 14 to 22 g, were used for the experiments with anti-hypophysis serum. Rabbit antisera were prepared by giving two subcutaneous injections of mouse hypophyseal cells incorporated into Freund's complete adjuvant and subsequent intravenous and intramuscular injections of mouse hypophyseal cells. Sera from bleedings on day 35, 42 and 49 after the onset of the injection schedule were prepared, inactivated at 56° C for 30 min and stored at –20° C. A single intraperitoneal injection of 0.15 ml. immune serum/5 g body weight was given. Control groups included mice injected with normal rabbit serum, and anti-thymus serum prepared in a manner similar to the anti-hypophysis serum.

Table 1 summarizes the results. Fifteen out of sixty-seven NMRI mice injected with anti-hypophysis serum died within 8–30 days after a single injection. Post-mortem examination showed that the thymus of these animals was completely atrophic. Before death they exhibited the typical clinical symptoms of wasting disease, such as pro-

Fig. 1. Thymus cortex of a normal NMRI male mouse, 30 days old, stained with haematoxylin and eosin. ( $\times 360$ .)

Fig. 2. Thymus cortex of a wasting NMRI male mouse, killed 10 days after a single intraperitoneal injection of rabbit anti-mouse hypophysis serum. Massive lysis and pycnosis of the cortex thymocytes. Stained with haematoxylin and eosin. ( $\times 360$ .)

Fig. 3. Thymus cortex of a wasted NMRI male mouse which died 12 days after a single intraperitoneal injection of rabbit anti-mouse hypophysis serum. The cell picture in the cortex is exclusively dominated by epithelial and reticular cells. Stained with haematoxylin and eosin. ( $\times 360$ .)

gressive loss of weight (for example, from 19–20 g to 13–14 g), ruffled hair, hunched posture, diarrhoea, oedema and inactivity. Animals injected with normal rabbit serum or with rabbit anti-mouse thymus serum showed a normal growth pattern.

Histological examination revealed a progressive loss of thymic cells after treatment with anti-hypophysis serum (Figs. 1–3). Fig. 2 shows one stage of the progressive disappearance of thymocytes, and Fig. 3 the final stage of a wasting animal in which thymocytes can no longer be observed in the thymus.

Fig. 4 shows the average growth curves of various groups of NMRI mice. The following experimental groups were used: (1) untreated controls; (2) mice wasting after treatment with anti-hypophysis serum; (3) mice treated with anti-thymus serum; (4) mice wasting after neonatal thymectomy. Untreated control animals and those treated with a single injection of anti-thymus serum behaved similarly except for the passing initial reduction in weight after the injection of the immune serum. Wasting animals injected with anti-hypophysis serum showed a growth pattern similar to the neonatally thymectomized mice. It must be emphasized that the mice were injected with the anti-hypophysis serum at approximately the age when they would develop the wasting syndrome if neonatally thymectomized. The results in Fig. 4 suggest that the age of the mice chosen for effecting the wasting by anti-hypophysis serum may be critical. Experiments are being performed to test this point.

It is interesting to note that in no experiment did all the animals treated with anti-hypophysis serum show the same pattern of wasting and thymus involution and a high percentage survived and grew in a normal way. This was at first attributed to the mice being of outbred NMRI strain. Similar results, however, were obtained with inbred mice. Fig. 5 gives a typical picture of individual growth curves and the time of death in C57/BL mice. Three out of eight animals wasted and died without thymus on day 8 or 9. One wasted but recovered and at the time of killing (day 31) had a normal thymus. One animal was wasting and when it was killed 21 days after the injection of antiserum it exhibited only very small

Table 1. WASTING SYNDROME AND THYMUS ATROPHY IN YOUNG ADULT NMRI MALE MICE AFTER A SINGLE INTRAPERITONEAL INJECTION OF RABBIT ANTI-MOUSE HYPOPHYSIS SERUM

remnants of thymus. Three animals had a normal growth pattern and when they were killed on day 31 they all had a normal thymus.

The observed differences in the growth pattern after treatment with anti-hypophysis serum seemed at first surprising. Although the injected male mice were of similar weight (14–17 g) and age (28–32 days), they did not belong to the same litter and therefore the differences may have resulted from the different stages of physical, and possibly sexual, maturity of the animals used. This suggests a hypophyseal mechanism regulating thymus growth and cell turnover, which is dependent on the age or maturity of the animal.

The animals wasting and dying with complete thymus atrophy after treatment with anti-hypophysis serum showed no macroscopic reduction or microscopic modifications of the lymph nodes and spleen as compared with mice injected with normal rabbit serum. No particular changes within sections of the pituitary of such mice were observed. The possibility that an alteration occurred in the adrenals, thyroid and gonads is at present being investigated.

*Modification of the hypophysis after neonatal thymectomy.* *NMRI* mice of the same litter were thymectomized or

sham-operated within 12 h of birth. The animals were killed at various times thereafter and serial transverse sections were prepared. (The techniques involved and detailed observations will be described elsewhere.) A marked degranulation of acidophilic cells in the anterior lobe of the pituitary was observed. This process seemed to be very pronounced about 20 days after thymectomy when the animals were still growing normally without outward signs of wasting disease (Figs. 6 and 7). These results lend additional support to the existence of a relationship between the thymus and the hypophysis. In agreement with earlier findings by Law *et al.*<sup>18</sup>, we did not find any signs of alteration in the hypophyses of thymectomized wasting mice.

These findings show that a single injection of rabbit anti-hypophysis serum given to young male mice may result in wasting disease, thymus atrophy or disappearance and death. The effect of anti-hypophysis serum seems to have a certain degree of specificity because anti-thymus serum and normal serum have no such effect on the thymus. In several experiments not reported here, repeated injections of anti-hypophysis serum did not result in toxic effects and there was no increase in the incidence of wasting. These findings indicate that a non-

Fig. 5. Growth of *C57/BL* mice after a single intraperitoneal injection of rabbit anti-mouse hypophysis serum. Dose of serum injected: 0.15 ml./5 g body weight. ○, No wasting, normal thymus (3); ●, wasting, no thymus (3); ×, wasting, recovering, normal thymus (1); □, wasting, killed, small thymus (1).

specific toxic effect or stress mechanism is not involved. The observed effects, however, are not seen in all animals of similar weight. Some animals waste but eventually recover and finally possess a normal thymus and most grow quite normally.

A striking observation was the similarity in the behaviour of neonatally thymectomized mice and young adult mice treated with a single injection of anti-hypophysis serum. Both groups of animals showed typical wasting disease which resulted in death. A likely explanation seems that there exists a direct relationship between the thymus and the hypophysis; namely, neonatal thymectomy results in changes in the hypophysis (Figs. 6 and 7) and wasting, while anti-hypophysis serum produces thymus atrophy and also wasting. The fact that after neonatal thymectomy mice start to waste at the time when injection of anti-hypophysis serum into young adults (28-32 days) produces wasting disease and thymus atrophy suggests that a close relationship may exist between hypophyseal and thymic factors which is dependent on age. Thymectomy or inhibition of the hypophyseal factors at a certain stage in the development of the animals results in wasting and death, thus indicating the possible significance of the thymus-hypophysis axis for growth, maturation and possibly differentiation. It is not known what factor(s) and/or cells are inhibited by anti-hypophysis serum. Based on the known growth

promoting effect of somatotrophic hormone on the lymphoid tissue and the thymus<sup>15</sup>, we would predict that this hormone should be capable of preventing the wasting disease in mice treated with anti-hypophysis serum. It seems likely that the thymocytes or one or more thymus factors are under the control of the somatotrophic hormone. Thymotropic hormone does not seem to be the essential factor because thyroxine promotes peripheral lymphoid tissue but not thymus growth<sup>16</sup>. The possibility that other unknown hypophyseal factors are acting directly on the thymocytes or on the epithelial cells of the thymus medulla cannot be excluded<sup>20,21</sup>.

According to Metcalf<sup>20</sup> and Everett *et al.*<sup>22</sup>, 95 per cent or more of the cells produced in the thymus are rapidly destroyed there, and thus it is likely that hypophyseal factors exist at a certain stage in the development which control the turnover of thymocytes through action on thymus target hormones or factors. Blockade of cells producing these factors by anti-hypophysis serum would result in only the destructive pathway being active.

The mode of action of anti-hypophysis serum is unknown. The effect on the hypophysis could be cytolytic, cytotoxic or else it could neutralize one or several hypophyseal hormones or factors. Recent experiments have shown that its activity can be absorbed out by hypophysis but not by thymus or spleen cells. A specific direct effect on the hypophysis is therefore likely. While no gross abnormality in the lymph nodes and spleen was observed, the absolute number of circulating leucocytes decreased sharply in the C57/BL wasting animals.

Thus, summing up, our experiments show that a single injection of anti-hypophysis serum given to young adult mice can result in wasting disease, thymus atrophy and death of the animals. Normal serum and anti-thymus serum have no such effects. Neonatal thymectomy results in morphological changes in the acidophilic cells of the anterior pituitary gland. These experiments complement each other and support the concept that there is a relation between the thymus and the hypophysis. Whether hormones in the hypophysis or some unknown factors are responsible for the reported findings has yet to be determined.

## ASTRONOMY

## Origin of Planetary Nebulae

STATISTICAL arguments have been advanced to demonstrate that all or a large fraction of stars with masses comparable with that of the Sun become planetary nebulae during the course of their evolution<sup>1,2</sup>. It has further been argued that these stars are the evolutionary products of horizontal branch stars, although the mechanism for the ejection of the expanding shell has remained a mystery.

Details of the structure of post horizontal branch stars, however, are now available from the work of Hayashi, Hoshi and Sugimoto<sup>3,4</sup>. They find that as the carbon-oxygen core grows in the centre of the star the luminosity increases up to  $8 \times 10^4$  L. This is considerably brighter than the luminosity at the time of the helium flash. As the star gets brighter the fraction of the star in the region of low temperatures increases, and if a sufficient fraction of the star is at temperatures below  $5 \times 10^4$  °K, with a consequent ratio of specific heats  $\gamma$  less than  $4/3$  due to hydrogen and helium ionization, then the possibility arises that the star will be dynamically unstable.

The stability of a star is determined by the equations for small perturbations about equilibrium. If the perturbations have a time dependence proportional to  $\exp(i\sigma t)$  then when  $\sigma^2$  becomes negative dynamical instability ensues. The eigenvalue equation that determines  $\sigma^2$  admits a variational principle, which gives<sup>5</sup>

$$\sigma^2 \leq \frac{\int_0^R \gamma p r^4 (d\xi/dr)^2 dr - \int_0^R r^3 \xi^2 [d(3\gamma - 4p)/dr] dr}{\int_0^R \rho r^4 \xi^2 dr}$$

where  $p$  is the pressure,  $r$  the distance from the centre of the star,  $\rho$  the density and  $\xi(r)$  any trial function for the proper eigenfunction that is finite at the centre and surface. If  $\gamma$  is constant and less than  $4/3$  for  $r \geq r_1$ , then a trial function  $\xi = (r - r_1)$   $r \geq r_1$ ,  $\xi = 0$   $r \leq r_1$ , gives  $\sigma^2 = 0$  when

$$\int_{r_1}^R p \left\{ \left( 5 + \frac{\gamma}{3\gamma - 4} \right) r^4 - 8r^3 r_1 + 3r^2 r_1^2 \right\} dr = 0$$

The critical value of  $r_1$  depends both on the value of  $\gamma$  and the variation of pressure with radius from  $r = r_1$  to  $R$ . The equation has been solved for  $p \propto 1/r^2$ ,  $1/r^4$ ,  $1/r^6$  for  $\gamma = 1, 1.1, 8/7, 1.2$ . The results are given in Table 1. If  $r_1/R$  is less than the value shown then the star is dynamically unstable.

Table 1. VALUES FOR  $r_1/R$  FOR DIFFERENT  $\gamma$  AND  $p$

$p/\gamma$	1.0	1.1	8/7	1.2
$\frac{1}{r^2}$	0.52	0.44	0.33	0.20
$\frac{1}{r^4}$	0.47	0.34	0.28	0.13
$\frac{1}{r^6}$	0.38	0.15	—	—

The detailed value of  $r_1/R$  as a function of luminosity and radius of a star could be calculated by solving the equilibrium and stability equations, but because of the uncertainty attached to the theory of convective energy transport, which is vitally important for giant stars, the above values given in Table 1 should be representative. From the models available we tend to prefer a value at the smaller end of this range.

It is instructive to compare these values with the fractional radius at which  $T = 5 \times 10^4$  as computed from

Table 2. DETAILS OF POST HORIZONTAL BRANCH STARS  
 $X = 0.900$   $Y = 0.099$   $Z = 0.001$

$M_2/M_\odot$	0	0	0.13	0.46	0.47	0.50	0.60
$M_1/M_\odot$	0.53	0.53	0.53	0.53	0.53	0.60	0.70
$\log(L/L_\odot)$	1.77	1.93	1.99	2.90	3.19	3.61	3.90
$r_1/R$	1	1	1	0.56	0.39	0.18	0.10

stellar models of the post horizontal branch stage of stellar evolution. Hayashi *et al.*<sup>3,4</sup> have only considered the core of the star whereas  $T = 5 \times 10^4$  occurs in the envelope. Fortunately we may use the relation  $T \propto 1/r$  outside the shell source with reasonable confidence, and from the known temperature and radius at the shell source calculate the radius at  $5 \times 10^4$  °K. Moreover, the total radius of the star is determined by its luminosity and scarcely affected by anything else so that the radius of the star can be calculated. The resulting values of  $r_1/R$  are given in Table 2.  $M_2$  is the mass of the carbon-oxygen core and  $M_1$  the mass interior to the hydrogen envelope.

As the luminosity increases up the tip of the giant branch—the last model is at the third helium flash—the depth of the unstable layer increases. By comparison with the value in Table 1 we see that we would expect the star to be dynamically unstable as it moves up the giant branch. This then is the mechanism proposed for the origin of planetary nebulae.

Because the structure of the giant is insensitive to the mass in the envelope unless this mass is less than about 4 per cent of the mass of the star<sup>6</sup>, we can see that almost all the envelope will be ejected, and we should expect a star of about  $0.7 M_\odot$  as the central star of planetary nebulae. The star will contract very quickly at first, and then cool down to become a white dwarf. The radius when the instability occurs will be about  $300 R_\odot$  giving the escape velocity comparable with the observed expansion velocities of the nebulae. If the total mass of the star was originally 1 solar mass there would be 0.3 solar masses in the envelope.

I thank Dr D. Osterbrock for helpful discussion. This work was supported in part by a contract from the US Air Force Cambridge Research Laboratories administered through the European Office of Aerospace Research.

## Bouncing Spheres in General Relativity

I REPORT here an analysis recently completed of the radial adiabatic motion of spherically symmetric models of uniform density and isotropic pressure in general relativity. An appropriate form of the metric is

$$ds^2 = 4F(t) \dot{R}^2 R^{-2} dt^2 - R^2 (r^2 dr^2 + d\theta^2 + \sin^2 \theta d\varphi^2)$$

with

$$R(t, r) = r \alpha(t) / [1 - r^2 \beta(t)]$$

$r$  and  $t$  being radial and time-like labels, respectively, and dots denoting differentiation with respect to  $t$ . At this stage  $\alpha(t)$  and  $\beta(t)$  are arbitrary functions of  $t$ , and

$$\frac{8\pi\rho}{3} = \frac{1}{4F(t)} - \frac{4\beta}{\alpha^2} = \frac{2m_s}{r_s^3} \left( \frac{1 - r_s^2 \beta}{\alpha} \right)^3$$

$$\frac{p}{\rho} = -1 + \frac{\dot{R}_s}{R_s} \frac{R}{\dot{R}}$$

suffix  $s$  referring to the surface of the model and  $m_s$  being the mass of the model according to the external Schwarzschild metric. It can readily be shown from this that

$$\frac{1}{2} \left( \frac{dR_s}{ds} \right)^2 = z - 2 \frac{x-1}{x^2}, \quad \left( x = 1 - \beta r_s^2, z = \frac{m_s}{R_s} \right)$$

where  $ds$  is the proper time of a co-moving observer on the surface of the model. Furthermore (with suffix  $c$  denoting the centre)

$$\rho = \frac{3z^3}{4\pi m_s^2}, \quad \frac{\rho}{\rho_c} = \frac{x}{z} \frac{dz}{dx} - 1.$$

Accordingly, imposition of a relation between  $\rho$  and  $p_c$  will give a track for the model in the  $(x, z)$  plane, real motion being confined to the part of the plane above and to the left of the curve (to be called  $Q$ )  $z = 2(x-1)/x^2$ . In particular, intersection of the model track and  $Q$  implies a bounce, that is, a reversal of motion. Attention has been concentrated on finding, for a given  $(p_c, \rho)$  relation, the ranges of initial values of  $z$  ("potential"),  $v = dR_s/ds$  ("velocity") and  $f = d^2R_s/ds^2$  ("acceleration") leading to a bounce after the initial inward motion. The initial acceleration is required if the  $(p_c, \rho)$  relation involves an otherwise unknown constant. The pressure density relations considered were of the form  $p_c \rho^{-\gamma} = \text{a constant}$  for  $\gamma = 1, 4/3, 5/3$ , together with the truncated form of the last two laws if the condition  $p_c \leq \rho/3$  is imposed. The corresponding curves in the  $(x, z)$  plane are power law type, straight lines and hyperbolae respectively.

A sample of the results obtained is the following set of conditions for the occurrence of a bounce.

If  $\gamma = 4/3$ , the minimum initial outward acceleration  $f$  leading to a bounce is found in terms of a quantity  $F = R_s f / z (\frac{1}{2} v^2)^{\frac{1}{2}}$ , where  $F = 2$  for small  $z$  and increases with  $z$ , more rapidly for large than for small  $v$ . For the largest permissible  $z$  (that is, giving finite  $p_c$ )  $F$  varies between 5.20 for  $v = 0$  ( $z = 0.4444$ ) and 10.56 for  $\frac{1}{2} v^2 = z = 0.2963$ . If the further restriction  $p_c \leq \rho/3$  is imposed a more complicated situation results. If initially  $\frac{1}{2} v^2 = z$ , no bounces are possible for  $z > 0.13396$  and bounces can occur without attaining  $p_c = \rho/3$  only if the initial  $z < 0.10993$ , the exact behaviour always depending on the initial acceleration.

If  $\gamma = 5/3$ , stable equilibrium configurations can occur for  $z < 0.23449$ , and oscillating models exist, but their largest  $z$  cannot exceed the value 0.34234. For general initial conditions, the most convenient quantity to consider is now the minimum initial value of  $w = (R_s f + z)/z^2$  as function of the initial  $z$  and  $v$ . For small  $z$ , the least value of  $w$  leading to a bounce is 10.93, increasing with  $z$  for large  $v$ , but decreasing with  $z$  for small  $v$ . The largest critical  $w$  value is 22.78 ( $\frac{1}{2} v^2 = z = 0.2963$ ); the smallest is 2.25 ( $v = 0, z = 0.4444$ ). Note that these positive  $w$  values imply negative  $f$  values (inward accelerations!) for reasonably small  $z$  ( $< 0.23449$  for  $v = 0$ ,  $< 0.1$  for  $\frac{1}{2} v^2 = \frac{1}{2} z$ ,  $< 0.084$  for  $\frac{1}{2} v^2 = z$ ). Again the imposition of  $p_c \leq \rho/3$  leads to greater complication. Bounces not involving  $p_c = \rho/3$  are now possible only from starting positions below the nearly straight curve (given in terms of the parameter  $q$ )

$$x = \frac{1}{2} q \left[ 3 \frac{2-q}{3-2q} \right]^{\frac{1}{2}}, \quad z = 2 \frac{q-1}{q^2} \left[ 3 \frac{q-1}{3-2q} \right]^{\frac{1}{2}}$$

which passes through (1, 0.0868) and (1.2, 0.2778), the latter being on  $Q$ .

For  $\gamma = 1$ ,  $R_s f / z = u$  is best considered as function of  $z$  and  $y = \frac{1}{2} v^2 / z$ . For small  $z$  the condition for a bounce is the same as in Newtonian theory, so that  $y$  and the minimum  $u$  are related by

$$y = (1+u) \log(1+u) - u$$

but for larger  $z$  the necessary  $u$  values become somewhat larger. For the largest  $z$  possible with the restriction  $p_c \leq \rho/3$  we still have  $u = 0$  for  $y = 0$ , but for  $y = 0.0328$ ,  $z = 0.2344$ ,  $u = 0.373$ ; and with  $y = 1$ ,  $z = 0.13396$ ,  $u = 2.732$ .

Full details of this work (which is related to two recent papers<sup>1,2</sup>) will be published elsewhere.

## PLANETARY SCIENCE

### Devitrification of Tektite Glass

THEORIES of the origin of tektites have usually been based on the assumption that tektite glass is stable. In view of the critical nature of this assumption, the tendency of various natural tektite glasses to crystallize has been studied by subjecting them to heat treatments for specified lengths of time. Two types of experiments were performed, one involving the heat treatment of supercooled glass above the strain point, and the other, crystallization of tektite liquid on slow cooling from the melt. The tektite samples used in these experiments were lent by R. S. Clarke, jun., of the Smithsonian Institution, and E. C. T. Chao of the US Geological Survey.

In order to study the devitrification of tektite glass, samples several cubic centimetres in volume were subjected to various heat treatments well below the liquidus temperature in an air atmosphere in an electric furnace. Only the outer skin of the glasses were subjected to air oxidation, and the oxidation state of the iron did not change in the interior, where crystallization was studied. Some identical samples were also treated in a vacuum furnace. Crystal morphology was studied microscopically and by X-ray diffraction.

Experiments designed to study the crystallization of cooling tektite liquids were performed by melting tektite glass and placing the molten material in a temperature gradient in the vicinity of the liquidus temperature for a period of about 24 h. These experiments were performed in platinum wound electric furnaces; the glass was contained in platinum boats. Obvious oxidation effects were again confined to the periphery of the sample.

Tektite samples listed in Table 1 were exposed to the heat treatment listed. Detailed descriptions will be summarized for the Vietnam, Pugad Babuy and Texas tektites. Fig. 1 shows that the tektites crystallized to two or three phases, denoted by  $A$ ,  $B$  and  $C$ . The Bohemian and Texas tektites did not crystallize to hypersthene, phase  $A$ ; phases  $B$ , cristobalite, and  $C$ , unidentified rod and shapes, were noted in these specimens.

Phase *A* crystallized in the form of transparent laths and rods. The index of refraction was greater than the surrounding glass, the cleavage traces were length slow (positive elongation) biaxial negative and the average size was 90–100 $\mu$ . Petrographic and X-ray diffraction identified phase *A* as hypersthene (Mg,Fe)<sub>2</sub>(SiO<sub>3</sub>)<sub>2</sub>, with diffraction lines at 3.18, 2.87, 2.53 and 2.45 Å (ref. 1).

Phase *B* crystallized in the form of 30° dendrites on the lath shapes of phase *A* (Fig. 2) and as isolated spherulites (Fig. 3). X-ray diffraction identified this phase as cristobalite, with lines at 4.09, 3.15, 2.85 and 2.50 Å. The cristobalite phase is apparently a modification of the more pure silica form, because it appears here with an index of refraction higher than that of the glass ( $N=1.51$ ). Substitution of alumina modified by alkaline earth ions in the cristobalite structure are suspected to account for the higher index.

Phase *C* was interspersed throughout the body of all the glass samples investigated. It appeared in the shape of small rods, T-shapes and Y-shapes. The 3–4 $\mu$  size and its high degree of dispersion in the glass made it difficult to identify either optically or by X-ray diffraction. Fig. 4 depicts phase *C*.

In addition to the tektites which were heat treated for 32 h, two samples from Vietnam were heated at 950° C for shorter periods of 2 and 10 h. These also crystallized to phases *A*, *B* and *C*.

Gradient furnace liquidus studies performed on both heating and cooling of Philippine Island tektites and artificial tektite glasses show the liquidus to be in the range 1,330°–1,350° C with tridymite and cristobalite as the phases at the liquidus. The test lasted for 24 h but similar results were obtained in 17 h.

The liquidus<sup>2</sup> temperature sets the upper limit of crystallization for the tektite compositions investigated.

It also shows that these glasses cannot be slowly cooled through the range 1,350°–950° C without substantial internal devitrification.

The fine grained internal crystallization of hypersthene which takes place rapidly on heating of the tektite glasses, particularly those from south-east Asia, is unknown among other high silica natural glasses. Such fine grained devitrification is frequently associated in artificial glasses with thermally induced micro-immiscibility or the formation of a fine emulsion of two glasses.

It is known that aluminosilicate glasses which contain appreciable amounts of ferrous ion tend to separate into two components, iron-silicate and aluminosilicate. The system leucite (KAlSi<sub>3</sub>O<sub>8</sub>)–fayalite (Fe<sub>2</sub>SiO<sub>4</sub>)–silica (SiO<sub>2</sub>) is an example of this. The stable liquid immiscibility occurs on the liquidus where an iron-silicate liquid coexists with a potassium–aluminosilicate liquid<sup>3</sup>. In the system Na<sub>2</sub>O–FeO–Al<sub>2</sub>O<sub>3</sub>–SiO<sub>2</sub> and FeO–Al<sub>2</sub>O<sub>3</sub>–SiO<sub>2</sub>, similar metastable immiscibility occurs. We propose that tektite glasses, which contain considerable FeO, separate on heating into a component rich in iron silicate and one rich in aluminosilicate. The iron silicate portion is unstable and devitrifies to ferro-hypersthene. The fine grain size is explained by the fine nature of the emulsion.

Cristobalite, or other phases, may form with increased heat treatment on the hypersthene nuclei. This results in a material of considerable crystallinity, which is very fine grained and resembles chert in appearance.

Fig. 1. Electron photomicrograph of a Pugad Babuy sample, USNM 2010, showing the three phases *A*, *B* and *C*. ( $\times c. 24,000$ .)

Fig. 2. Phase *A*, laths; phase *B*, dendrites. ( $\times c. 70$ .)

Fig. 3. Cristobalite spherulites.

Fig. 4. Phase C rods, Y-shapes. ( $\times c. 700$ .)Fig. 5. Cooling curves for tektite spheres. Thermal diffusivity ( $k$ )  $= 5 \times 10^{-3} \text{ cm}^2/\text{sec}$ .

The rate of devitrification of tektite material on cooling from a melt depends on the relative stability of liquid and crystal; the rate on heating from cold glass depends on the stability of the glass towards both immiscibility and crystal formation. Artificial high silica and aluminosilicate glasses which contain soda and potash are known to be very resistant to devitrification, while iron and magnesium aluminosilicates are usually unstable and devitrify more readily.

It has been noted from the heating experiments described that the tendency for the hypersthene devitrification on heating is greatest in the philippinites and indochinites, and least among the moldavites and North American tektites. This tendency seems to be related to composition (Table 2). Tektites, poor in silica, particularly those richest in FeO, MgO and  $\text{Al}_2\text{O}_3$ , would be expected to devitrify most readily, while tektites with more silica, particularly those richest in the alkalis, would be expected to be more stable glasses.

The great instability of the indochinites low in silica, which transform to cherty hypersthene crystal bodies when heated for 2–10 h above  $900^\circ \text{C}$ , suggests that tektites with even less silica may exist, but if they do they are in a devitrified form difficult to distinguish from many common rocks. It is possible that diligent searching in fields strewn with tektites will uncover crystalline materials which are tektitic in origin.

The susceptibility of tektite glass to internal devitrification sets rigid limits on the maximum size of a molten tektite body which can cool to a rigid condition and still

remain a glass. The key parameter in such a calculation is  $k$ , the thermal diffusivity, which has been measured at Corning Glass Works for a typical indochinite composition glass. This parameter has a value of about  $5 \times 10^{-3} \text{ cm}^2/\text{sec}$  in the general temperature range of interest. From the heat equation with spherical co-ordinates, as shown in Fig. 5, time-temperature curves can be drawn which can be used to determine the critical size of a tektite. According to this equation, a sphere 5 ft. in diameter of tektite liquid at  $2,000^\circ \text{K}$ , the surface of which is quenched and held at  $0^\circ \text{K}$ , would cool so slowly that its centre would remain at a temperature of  $950^\circ\text{--}1,350^\circ \text{C}$  for more than 10 h. This is sufficient time for a typical indochinite-philippinite tektite to devitrify. Radiative cooling from the surface would involve even slower cooling rates than quenching to absolute zero; a 5-ft. sphere can therefore be considered a maximum size for any cold entirely glassy tektite body of the indochinite type which has cooled from a temperature in excess of its liquidus temperature.

The tendency for hypersthene to devitrify as fine microlaths on short heating of many south-east Asian tektite glasses above  $900^\circ \text{C}$  limits the thermal history of susceptible glasses which do not display devitrification. Such glasses must never have been reheated above  $900^\circ \text{C}$  for more than a few hours subsequent to their last period of fusion.

The ease of internal crystallization of south-east Asian tektite glass on slow cooling severely limits the size of the parent mass, unless this mass was either not formed by conventional melting above the liquidus, was substantially crystalline, or was never cooled below the liquidus before breaking up into smaller fragments.

We thank R. S. Clarke, jun., and the US Geological Survey, for the loan of tektite samples, D. L. Evans and B. Boller for their assistance in the X-ray diffraction work, and G. B. Carrier for electron photomicrographs.

### Ionospheric No-echo Occurrences

THE use of ionogram data to identify periods of high absorption has recently been criticized by Schaeffer<sup>1</sup>. This criticism is justified at a number of stations, including Mawson, but does not apply to stations where adequate precautions are taken in the ionogram analysis. At Halley Bay, in particular, it is relatively easy to obtain high sensitivity of the ionosonde down to 0.7 Mc/s by using

large aeriels, so that changes in the frequency minimum,  $f_{\min}$ , detect only large changes in absorption.

Every no-echo event at Halley Bay during the IGY and IQSY was scrutinized, taking into account background noise level, the value of critical frequency immediately before and after the "blackout" and any evidence for tilts which would be expected if the critical frequency had fallen during the "blackout" record. Because more than half the "blackouts" seen at Halley Bay last for half an hour or less and ionograms are available for every quarter hour, these controls are very effective in preventing misinterpretations and it is not expected that more than 1 per cent of the total "blackouts" recorded could be challenged on the grounds raised by Schaeffer.

The diurnal variation of the  $F_2$  layer critical frequency was examined on the days which showed no-echo conditions and compared with the corresponding variation for other days. These showed no significant differences of the type suggested by Schaeffer; in fact, as would be expected from disturbed to quiet day ratios of the critical frequency of the  $F_2$  layer,  $f_oF_2$ , at Halley Bay, the critical frequencies were somewhat higher than normal on the days with no-echo conditions. As an additional check, a high sensitivity absorption equipment (A.1) was used during many of the events. This clearly showed increased absorption with normal heights of reflexion whenever echoes were received during the recovery stage.

Despite the widely different critical frequencies in the IGY and IQSY, the "blackout" phenomena reported by Bellchambers and Piggott<sup>2</sup> have recurred, at a lower rate of occurrence but at essentially the same times as in the IGY, and have shown the same relation to magnetic activity. In both epochs auroral types of high absorption are often present at times when the magnetic field is undisturbed, particularly near 1900 L.M.T. Most of these periods are seen within 12 h of classical events of high planetary magnetic disturbance index.

Piggott and Shapley<sup>3</sup> and others have pointed out that riometer absorption events often differ greatly from those found using ionosonde or by field strength measurement at lower frequencies. This is because the riometer is relatively more sensitive to absorption processes where the collisional frequency is high, typically below 75 km, whereas the other techniques are relatively more sensitive to absorption at greater heights. One would expect different spatial and temporal distributions for particles capable of ionizing the atmosphere in these two regions.

## MOLECULAR STRUCTURE

### Charge Transfer Complexes of Lipids with Iodine

THERE is much interest in the role of charge transfer interactions in biology<sup>1</sup>. In a study of the semiconductive properties of lipids in the solid state, Rosenberg and Jendrsiak (ref. 2 and unpublished work) have shown that when lipid molecules, such as egg lecithin and synthetic lecithin, are exposed to iodine vapour, they exhibit a large increase in electrical conductivity with a concomitant decrease in the activation energy from the dry state value. They suggest that a charge transfer mechanism may be involved. Because they also found that iodine added to the aqueous media surrounding

Fig. 1. Absorption spectra of lecithin and iodine in carbon tetrachloride. a,  $1.18 \times 10^{-4}$  molar egg lecithin; b,  $6.21 \times 10^{-3}$  molar synthetic lecithin;  $5.63 \times 10^{-2}$  molar iodine.

lipid bilayers (egg lecithin or oxidized cholesterol) increased the bilayer conductivity also by a factor of more than  $10^4$ , it was suggested that a charge transfer mechanism might also be involved in this case. It was with the intention of investigating these possible charge transfer mechanisms that we undertook the work reported here.

When iodine in carbon tetrachloride was added to a solution of lipids in carbon tetrachloride, the original violet colour of iodine changed. In the case of lecithin (synthetic and egg) two new absorption bands appeared in the region of 366  $\mu$  and 294  $\mu$ . By varying the concentrations of iodine and lecithin, both dissolved in carbon tetrachloride, it was found that the new bands arose from a 2 : 1 complex between lecithin and iodine. One mechanism of the reaction might be represented by

According to Mulliken<sup>3</sup> this would be the inner complex, whereas the outer complex ( $\text{lecithin} - \text{I}_2$ ) would be a molecular complex of the usual type. This inner complex is an essentially ionic structure and it slowly dissociates as

As soon as  $\text{I}^-$  forms it combines with free  $\text{I}_2$  molecules to give  $\text{I}_3^-$ , which is responsible for the bands at 366  $\mu$  and 294  $\mu$ . The spectra of lecithin (egg and synthetic) with iodine are shown in Fig. 1. The optical density of these solutions increased with time and thus all the spectra were recorded within 30 min of mixing the solutions. Of the two lecithins, egg lecithin is more than a hundred times stronger than synthetic lecithin in forming the complexes as observed from the change in optical density of the same concentration of iodine with different concentrations of lecithin.

Iodine, on the other hand, was found to form an outer complex with cholesterol. The visible iodine band at 518  $\mu$  ( $\epsilon = 935$ ) shifted to 509  $\mu$  ( $\epsilon = 800$ ) and at the same time a new band appeared at 332  $\mu$  where both donor and acceptor have no absorption. This band of iodine and cholesterol at 332  $\mu$  was considered to be a charge transfer band. By varying the concentrations of cholesterol and iodine in carbon tetrachloride, it was found that the new band came from a 1 : 1 complex formation. Applying the Ketelaar equation<sup>4</sup> at the  $\lambda_{\max}$  of the complex, the equilibrium constant was estimated, using a donor concentration range of  $9.68 - 48.40 \times 10^{-3}$  moles/l. with a fixed concentration of acceptor of  $11.26 \times 10^{-4}$  moles/l. The results are  $K = 6.26$  l./mole and  $\epsilon_{\max} = 795.0$ . With the aid of the equilibrium constant value, we can record the absorption curve, which results entirely from the charge transfer complex, by balancing the solution of the complex against the concentrations of free donor and free acceptor present in the solution of the complex. For this purpose we used four 1 cm silica cells,

Fig. 2. Absorption spectrum of oxidized cholesterol and iodine in carbon tetrachloride. *a*,  $11.3 \times 10^{-4}$  molar iodine; *b*,  $1.28 \times 10^{-3}$  molar oxidized cholesterol and  $11.3 \times 10^{-4}$  molar iodine. (In *b* the OD shown is twice the experimental OD.)

two in each compartment. The results are shown in Fig. 2.

Because the lipid bilayers are 70 Å thick and about 1 mm in diameter, it was not possible to study spectroscopically their interaction with iodine. As an approximation to the interaction of the bilayer system with iodine, we decided to study the spectra of egg lecithin in water and its interaction with iodine. Egg lecithin, dispersed in water, is thought to have a micellar structure. The micelles are supposedly disk-like structures with a disk thickness of about 70 Å—about the thickness of a lipid bilayer<sup>5</sup>. The polar groups are presumably exposed to the water, whereas the hydrocarbon chains are in the interior. The interaction of this lipid system with iodine should be quite similar to that of the bilayer. We did not attempt to disperse oxidized cholesterol in water.

Aqueous iodine exhibits the spectra of the tri-iodide ion ( $\lambda_{\max} = 351 \text{ m}\mu$  and  $287 \text{ m}\mu$ ) and that of molecular iodine ( $\lambda_{\max} = 460 \text{ m}\mu$ ). When a dispersed aqueous solution of egg lecithin was added to the same solution of iodine, we found that the molecular iodine band at  $460 \text{ m}\mu$  decreased, whereas the tri-iodide ion bands increased. We obtained the same result when we added small amounts of sodium iodide to the aqueous solution of iodine. The results are shown in Fig. 3.

The spectra of thin films of egg lecithin in the solid state were also studied. The films were formed by evaporating the chloroform from a few drops of a 0.02 molar solution of lecithin and chloroform, placed on one flat surface of a 5 cm quartz cell. Because quartz was also the substrate used for the electrical measurements of the thin films (our unpublished work), the two situations should be comparable. The films were dried with helium gas and then a crystal of iodine was placed in the quartz cell and allowed to sublime. The free iodine was evacuated at low temperature. The spectra of iodine–lecithin in the

Fig. 3. Absorption spectrum of egg lecithin and iodine in water. *a*,  $1.53 \times 10^{-3}$  molar egg lecithin dispersed in water; *b*, about  $4 \times 10^{-4}$  molar iodine in water; *c*, egg lecithin and iodine in water (concentrations same as in *a* and *b*)

Fig. 4. Spectrum of egg lecithin film exposed to iodine vapour. Film is on quartz. *a*, Egg lecithin film on quartz; *b*, egg lecithin film exposed to iodine vapour, on quartz.

solid state showed two bands, at  $370 \text{ m}\mu$  and  $295 \text{ m}\mu$  (Fig. 4), which are similar to those obtained in the aqueous system—that is, the short wavelength band is more intense than the long wavelength one. From this result and also from the study of spectra in aqueous solutions, it may be concluded that lecithin forms a molecular charge transfer complex with iodine both in the solid state and in aqueous solution. Oxidized cholesterol could not be laid down as a film, unfortunately, and no spectra could be taken.

Because the  $I_3^-$  bands are seen for the lecithins in organic solvents, water and in the solid state, it appears that the same type of interaction occurs between the lipid and iodine in all three cases. This is interesting in view of the proposed states of lecithin in the various cases. The micellar form in water, and the bilayer leaflet in the solid state are similar, but lecithin dissolved in a non-polar solvent does not change the dielectric constant; the lecithin behaves as if its polar groups were neutralized<sup>5</sup>. This suppression of the dipole moment has been explained by the formation of molecular associations, in agreement with the results of molecular weight measurements, and is thought by some workers to indicate some sort of aggregate structure with the polar groups directed toward the interior and the hydrocarbon chains toward the exterior. Nevertheless, the iodine seems to react similarly with the lecithin in the non-polar solvent, in the polar solvent and in the solid state. Moreover, because the interaction of iodine and lecithin appears to be of the same type for a dispersion of lecithin in water (taken as an approximation to the lipid bilayer case) and for lecithin in the solid state film, the changes in electrical conductivity which result may well arise from the complex formation in both cases. If, indeed, these are charge transfer reactions, it seems that electronic conduction should be considered as a possibility in both cases. The same ideas may apply to oxidized cholesterol. The nature of this charge-transfer complex should be the subject of further investigation.

This work has been supported by a contract from the US Office of Naval Research.

## Molecular Orientation of Fibres by Polarized Internal Reflexion Spectroscopy

SUCCESSIVE drawing of synthetic fibres increases the molecular orientation of the polymer chains and is a method which is widely used for improving the tensile properties of yarns. Investigations of the changes in the dichroism of individual infra-red modes of the polymer with polarized infra-red radiation have yielded important conclusions regarding the structure and band assignments<sup>1</sup>. The dichroism of each infra-red mode, expressed as a dichroic ratio, is related to its transition moment; the angle of inclination of the bond to the molecular axis; and the degree of molecular orientation. Measurement of the dichroism of nylon fibres by infra-red transmission techniques has been introduced<sup>2</sup> and questioned<sup>3</sup> because sample preparation by microtoming can alter the existing orientation. Internal reflexion spectroscopy<sup>4</sup>, however, provides a non-destructive, rapid and reproducible method for obtaining the surface dichroism of any oriented fibre or film—measurements which are difficult or impossible to obtain by conventional transmission techniques.

An internal reflexion attachment<sup>5</sup> was designed for use with commercial, double-beam spectrophotometers. A trapezoidal germanium prism, providing twenty-one internal reflexions, is placed at a focal point in each beam. Prism holders apply a known and constant hydraulic pressure against the sample and the prism surface to obtain sufficient and reproducible optical contact. A polished germanium reflexion polarizer<sup>6,7</sup> is fixed in front of the monochromator entrance slit. Polarization efficiency in excess of 99 per cent is obtained with a single reflexion from the polarizer surface. First surface mirrors in the polarizer unit return the beam to the optical axis of the spectrophotometer.

To obtain the dichroic ratio, two infra-red spectra are obtained for each fibre at the same contact pressure. Initially, the fibres are placed against the surface of the internal reflexion prism with the incident electric vector parallel to the axis of the fibre. The fibres are then rotated through 90° and the spectrum with perpendicular incidence is obtained. The dichroic ratio is calculated from the ratio of the absorption intensities for the parallel to perpendicularly polarized light at each infra-red mode.

The dichroic ratios for a series of drawn 66 nylon fibres at six frequencies are given in Table 1. The dichroic ratios for a pressed film were obtained for the draw ratio of unity. It was determined that the surface dichroic ratios obtained by internal reflexion spectroscopy are directly related to the bulk birefringence for fibres having a draw ratio of more than 1.4. For values of the draw ratio less than 1.4, the surface of the fibre appears to have greater orientation than the interior.

Table 1. DICHROIC RATIOS FOR A SERIES OF ORIENTED 66 NYLON FIBRES OBTAINED BY INTERNAL REFLEXION SPECTROSCOPY AT VARIOUS INFRA-RED ABSORPTION FREQUENCIES

Dichroism	Frequencies (cm <sup>-1</sup> )	Group assignments <sup>a</sup>	Draw ratios				
			1.00	1.40	2.27	3.76	5.03
Perpendicular bands	3,310	$\nu$ (NH)	1.03	0.69	0.57	0.34	0.36
	3,080	$\nu$ (NH-H)	0.94	0.67	0.56	0.45	0.37
	1,640	$\nu$ (C=O) I	1.01	0.85	0.74	0.46	0.43
Parallel bands	1,538	$\nu$ (NCO) + $\delta$ (NH) II	1.02	1.08	1.40	1.88	1.85
	1,277	$\delta$ (CNH) III	1.03	1.08	1.75	2.20	2.00
	1,200	$\delta$ (CH)	1.01	1.03	1.53	2.01	1.85

$\nu$  = stretching,  $\delta$  = bending, in plane.

Quantitative polarization data obtained in this way are very sensitive to small changes in surface orientation at low draw ratios. The polarized internal reflexion technique therefore complements the X-ray diffraction method for measuring orientation—a method which is most useful for fibres of high molecular orientation. A satisfactory spectrum for each angle of polarization can be obtained without modification or deformation of the

fibre, regardless of its diameter, surface condition, amount of dye or pigment content.

## THE SOLID STATE

### Substitution by Iron in Kaolinite

KAOLINITE often occurs in admixture with other minerals (for example, micas and iron oxides) in which iron is a legitimate constituent. Because of the difficulties of detection and separation, it has always been doubtful whether iron actually substitutes in the kaolinite lattice. We provide here evidence for substitution of iron(III) in the octahedral (Al) sites.

The materials studied were the fractions of two clays from the St. Austell area with equivalent spherical diameters of 1–2.5 $\mu$ . These were subjected to repeated extraction in an inhomogeneous magnetic field as 16 per cent solid suspensions deflocculated at pH 8.0 with 0.1 per cent w/w tetrasodium phosphate.

Fig. 1. Plot of the content of mica against the concentration of  $\text{Fe}_2\text{O}_3$  for magnetic extracts of clay samples A and B.

Fig. 1 shows a plot of the content of mica against the total content of iron (as  $\text{Fe}_2\text{O}_3$  determined chemically) for those magnetic extracts of samples A and B which have been analysed. The contents of mica, tourmaline and feldspar were deduced from X-ray powder photographs. A positive intercept on the abscissa is obtained for both clays, indicating that repeated extraction would yield a fraction containing no mica but 0.5 and 0.8 per cent  $\text{Fe}_2\text{O}_3$  for A and B respectively. This residual iron is not extractable by acid washing. Chemical analysis of the highly refined specimens of A and B yields the following:

	Percentage by weight	
	<i>A</i>	<i>B</i>
Fe <sub>2</sub> O <sub>3</sub>	0.31	0.37
FeO	0.002	0.003
K <sub>2</sub> O	0.08	0.28
Na <sub>2</sub> O	0.03	0.09
Ignition loss	14.02	13.96

If it is assumed that the mica fraction of each magnetic extract contains all the K<sub>2</sub>O found, the mean K<sub>2</sub>O contents of the micas in *A* and *B* are found to be 5.8 and 8.5 per cent respectively. On this basis, the mica content of the refined materials would be 1.4 and 3.3 per cent respectively. If this mica contained all the residual iron, the Fe<sub>2</sub>O<sub>3</sub> concentrations of iron in the mica would be 23 per cent and 11 per cent respectively, which are higher values than found for any micas actually extracted from kaolinite in the particle size considered. Furthermore, X-ray diffractometry indicates that the mica content of the refined clays is <0.12 and <0.19 per cent respectively. No mineral other than kaolinite could be detected.

These findings provide *prima facie* evidence for iron substitution in kaolinite and this is confirmed by Mössbauer effect measurements. While these analyses were in progress, Weaver *et al.*<sup>1</sup> published results of a Mössbauer survey of clay minerals including kaolinite. Their kaolinite (from an American source) contains much more iron, however, and the impurity concentration was uncertain.

Fig. 2 shows a typical Mössbauer plot of transmission against velocity for the dioctahedral mica, muscovite (from Lee Moor, Devon). The source used was 10 mc. of cobalt-57, yielding the iron-57 14.4 keV  $\gamma$ -ray. Two quadrupole doublets *XX'* and *YY'* are observed. *XX'*

Fig. 2. Mössbauer spectrum of muscovite.

Fig. 3. Mössbauer spectrum of magnetic extract *L*.Fig. 4. Mössbauer spectrum of magnetic extract *M*.Fig. 5. Mössbauer spectrum of refined kaolinite *A*.

Fig. 6. Mössbauer spectrum of gibbsite.

has an isomer shift and quadrupole splitting characteristic of iron(II) and *YY'* is characteristic of iron(III). Figs. 3 and 4 show similar spectra for magnetic extracts of sample *A* corresponding to points near *L* and *M* on the curve of Fig. 1. These show progressive diminution of *XX'* compared with *YY'* as the mica content is reduced (that is, an increase in the ratio of iron(III):iron(II)). Fig. 5 shows a spectrum of highly refined kaolinite *A*. The ferrous doublet has now almost disappeared and the position of the residual iron(II) line *X'* is shifted to lower velocity. The ferric lines (*YY'*) are relatively enhanced and have a smaller quadrupole splitting than those in

muscovite. The spectrum of iron in gibbsite ( $\text{Al}(\text{OH})_3$ ) (Fig. 6) shows a ferric doublet closely similar to that of kaolinite. The results are summarized in Table 1.

Table 1

Material	Iron (II)		Iron (III)	
	Isomer shift	Quadrupole splitting	Isomer shift	Quadrupole splitting
Muscovite	$1.20 \pm 0.05$	$2.98 \pm 0.05$	$0.48 \pm 0.04$	$0.72 \pm 0.05$
Kaolinite		$\sim 2.25$	$0.48 \pm 0.04$	$0.50 \pm 0.05$
Gibbsite			$0.47 \pm 0.04$	$0.52 \pm 0.05$

Isomer shifts are relative to stainless steel. All values are in  $\text{mm sec}^{-1}$ .

The following conclusions can be drawn.

(a) The principal contaminant containing iron in the unrefined kaolinite is mica of the muscovite type, to which the iron(II) doublet in the Mössbauer spectrum is largely due. (Tricathedral biotite shows a smaller iron(II) quadrupole splitting.)

(b) Genuine lattice substitution by iron(III) does occur in kaolinite. Because the iron in refined kaolinite is not extractable in acid, it cannot be due to oxides or to goethite ( $\text{FeO} \cdot \text{OH}$ ) (possibly present in the sample used by Weaver *et al.*<sup>1</sup>). The possibility that the iron(III) doublet arises from small superparamagnetic grains of  $\alpha\text{-Fe}_2\text{O}_3$  (ref. 2) has been rejected because, at room temperature, the spectrum of  $\alpha\text{-Fe}_2\text{O}_3$  particles large enough to give the observed quadrupole splitting should contain a substantial six-line component due to magnetic hyperfine interaction in antiferromagnetic  $\alpha\text{-Fe}_2\text{O}_3$ . Spectra at  $80^\circ \text{K}$  for muscovite and biotite confirm that the iron(III) doublet observed in these materials does not result from this cause.

(c) The similarity of the iron(III) doublet in kaolinite and gibbsite (in which iron(III) ions in the Al sites are certainly octahedrally co-ordinated) suggests that the substitution of iron in kaolinite is also in the octahedral sites.

(d) A small amount of iron(II) substitution in kaolinite is suggested by the fact that the iron(II) line in the kaolinite spectrum is not in the position expected for muscovite.

## BIOPHYSICS

### Electrically Active Polyelectrolyte Membranes

SEVERAL lipid membranes<sup>1,2</sup> have been described as models for neuronal and other cell membranes, usually based on the lipid bilayer concept of Davson and Danielli<sup>3</sup>. Such membrane models have the characteristics of insulators with a high specific resistivity and dielectric strength. They can, however, be changed with certain protein additives, notably the excitability inducing materials of Rudin and Mueller<sup>4</sup>, to produce membranes with some biological properties. Thus either the protein alone or the protein lipid complex is the important factor for converting the insulator properties of lipids to those resembling biological membranes. This paper describes the preparation and properties of specially prepared polyelectrolyte membranes, containing no lipids, which under a d.c. electric field can spontaneously generate

Fig. 1. Experimental arrangement:  $R_1, R_2, R_3$  are 50,000 ohms resistances;  $E_1, E_2, E_3, E_4$  are silver-silver chloride electrodes;  $C_1 = C_2 = 0.15$  normal sodium chloride;  $V$ , voltmeter;  $A$ , microammeter;  $C.F.$ , cathode follower; and  $S$ , scope. Enlargement shows the membrane composition with a polybase layer  $A$ , a polyacid  $B$  and a polysalt interface.

transients with time constants and amplitudes analogous to the spike potentials of neuronal membranes.

The membranes are prepared by reacting a solution of polymeric acid with a polymeric base to give a polymeric salt at the interface. The polyacid, a 10 per cent solution of a co-polymer polyacrylic acid and acrylamide (80/20) in 0.15 normal sodium chloride, adjusted to pH 4.5 with sodium hydroxide, is placed as the lower layer in the Petri dish of the experimental arrangement in Fig. 1 and allowed to react with the polybase, 2 per cent dimethylaminoethyl acrylate, in 0.15 normal sodium chloride, for about 30 min to generate the polyampholyte membrane. The membrane is then carefully washed *in situ* by repeated dilution of the polyacid layer with 0.15 normal saline and draining of the excess fluid. Similarly the upper polybase layer is washed with saline to produce a membrane separating two equal salt solutions (0.15 normal sodium chloride). Silver-silver chloride electrodes are then placed into the electrode holders, and a negative and positive electrode are applied to the polybase and polyacid layer respectively. The system is monitored at the upper surface by means of a third silver-silver chloride electrode, and voltage changes are amplified and displayed as voltage spikes on an oscilloscope. The firing pattern of a given membrane is photographed for further analysis. It is essential that the indicated polarity be maintained and that the membrane should be devoid of imperfections so that it can truly behave as a barrier.

When the d.c. potential is gradually raised, the membrane begins to generate spikes spontaneously at a critical applied voltage. Typical records of the observed membrane activity are shown in Fig. 2. The pattern of firing consists of spikes of varying amplitude (1–120 mV) and duration (the half width of the spikes is between 2 and 10 msec). When the voltage applied to the membrane is raised beyond the critical firing level an increased firing rate is observed and then at a higher applied voltage firing suddenly ceases and there is a constant current flow through the membrane. These voltage variations can be repeated many times without loss of the spontaneous activity properties. Analysis of the shapes of the spikes shows that there is a very fast rise time in the development of a spike followed by a slower decay and inversion of current flow. This reversed current flow usually takes a longer time than the period of the main spike and may last as long as 50 msec.

One of the requirements for the generation of spikes apparently is the presence of salt on both sides of the membrane. Thus distilled water on both sides gives no firing, whereas 0.02, 0.05, 0.15 and 0.2 normal electrolytes on both sides of the membrane give spontaneous spike generation which continues for hours. The critical voltage

Fig. 2. Oscilloscope traces of spike generated by polyelectrolyte membranes.

for initiation of spikes does not appear to be constant, but varies with each new membrane, which suggests a dependence on the membrane thickness. In a typical experiment, the critical voltage for firing was 0.7 V across the membrane plus electrolyte and the voltage for stopping the firing was 1.3 V. An interesting feature of these membranes is that near the critical firing voltage region, the output of the recording electrode becomes sensitive to mechanical vibrations. This ceases once the firing level is reached.

One variation of this phenomenon is the use of calcium polyacrylate as the membrane component formed by the reaction of a dilute solution of calcium hydroxide with polyacrylic acid at an interface. Such a membrane will also spontaneously generate spikes under a d.c. electric field.

The empirical resemblance of the properties of polyelectrolyte membranes to certain aspects of neuronal membranes is clearly evident. The generation of spikes of the right order of magnitude and shape, the existence of a critical voltage for firing and a higher voltage for cessation of firing suggest that these membranes should be useful models for studying the mechanism of spike generation. Moreover, the simplicity of the model offers a means for independent studies of the "spike" generation mechanisms from those which originate the membrane resting potential of a neurone.

In a recent discussion with Katchalsky, he suggested that current flow through the membrane results in accumulation of salt into the polyampholyte layer, the sodium and chloride ions arriving from opposite sides of the membrane, and at a critical salt concentration the swollen polyelectrolyte membrane shrinks and produces a breakdown region. The electrolyte washes off the excess salt to re-establish the original state of the membrane. Experiments to explore the various physicochemical aspects of these polyelectrolyte membranes and their use as models for biological systems are in progress.

## RADIOBIOLOGY

### Effect of High Dose Rates on Survival of Mammalian Cells

THE increasing use in radiobiology of pulsed sources of radiation and very high dose rates makes it desirable to study the effects of this type of radiation on biological systems. This paper describes the differences in the survival of cells when exposed to radiation delivered in a single pulse or in two pulses.

The source of radiation was the 15 MeV Mullard linear accelerator at St. Bartholomew's Hospital<sup>1</sup>. It produces an electron beam in pulses lasting 1.3  $\mu$ sec, which can be given either singly or as a series of pulses with a variable repetition frequency. In this work, the output of the accelerator was kept approximately constant and different doses were obtained by placing the samples at different distances from the exit window; thus the exposure time was constant and the dose rate was proportional to the dose. The maximum dose used was 4,500 rads in one pulse, corresponding to a mean dose rate of  $3.5 \times 10^8$  rads/sec.

The dose delivered was measured by using lithium fluoride thermoluminescence dosimetry; this was checked by ferrous sulphate and red 'Perspex' dosimetry<sup>2</sup>. The error in the dose delivered, chiefly caused by the spatial distribution of the beam, was 2 per cent at 200 rads, rising to 10 per cent at 5,000 rads.

The biological system used was a sub-clone of HeLa S-3 cells, obtained from the Radiobiology Laboratory at Oxford. The cells were irradiated in suspension at 25°C, 24 h after collection; they were then diluted and assayed for survival by the Puck technique.

In the first series of experiments, the cell suspensions were corked in polystyrene bottles after routine handling in the presence of air. Irradiations were carried out to give either single pulses or two pulses separated by 2.5 msec. The results are shown in Fig. 1. The solid line is the fitted regression line for the two-pulse data. It can be seen that the single-pulse data follow the two-pulse line very closely up to about 900 rads, but for larger doses the cells irradiated with a single pulse show a greatly reduced sensitivity.

This biphasic nature of the single pulse survival curve is thought to be caused by the removal of oxygen from the relevant site within the cell by its reaction with the radical intermediates formed during the irradiation. As the dose in the pulse is increased the concentration of oxygen will be reduced, but because the cell sensitivity remains almost constant until about 90 per cent of the oxygen in an air-equilibrated system has been removed<sup>3</sup>, the change from oxic to anoxic sensitivity will occur in a relatively small dose range. In this system, the radiobiologically relevant oxygen is apparently removed by a dose of about 900 rads during the 1.3  $\mu$ sec pulse.

In order to check whether the effect observed is indeed caused by the removal of oxygen, a second series of experiments was carried out in which an inert antifoam agent was added to the cell suspension, and either air or

Fig. 1. HeLa cell survival curves following irradiation in static aerobic suspensions with one or two pulses of 14 MeV electrons. (Errors generally smaller than the points.) ●, One pulse; ○, two pulses:  $D_0 = 206$  rads.

nitrogen was bubbled through for 5 min before and during the irradiation. The results are shown in Fig. 2. It can be seen that for irradiation in hypoxic conditions the single and double pulse data both follow the same line which has a slope approximately 2.5 times smaller than that of the line for air. In this case too, the single pulse curve for air changes in slope after a dose of about 1,000 rads.

The fact that the survival curves in hypoxic conditions show no change in cell sensitivity in the range 0–4,500 rads may be taken as confirmation that oxygen depletion during the pulse is responsible for the biphasic nature of the single-pulse air survival curve.

Data from simple air-equilibrated chemical systems<sup>4</sup> suggest that the dose required for oxygen depletion is of the order of 50 krad. The results of Dewey and Boag<sup>5</sup> using pulsed irradiation of bacteria are in agreement with this figure, as also are recent measurements in this laboratory using an oxygen cathode technique. In the mammalian cell system used in the present study, a much smaller dose is required to produce oxygen depletion. This suggests

Fig. 2. HeLa cell survival curves under gas equilibration by bubbling air or nitrogen through the suspensions. The initial slope of the broken line is that of Fig. 1, and the second portion was drawn parallel to the nitrogen line. ●, One pulse; ○, two pulses.

that in the vicinity of the sensitive sites within the cell either the equilibrium oxygen concentrations are much lower, or the G-value for the removal of oxygen is much higher than the values in the extracellular medium. In contrast, the results of Dewey and Boag indicate that in the bacterial cell both these parameters are the same as in the surrounding medium. Experiments are in progress to determine total intracellular oxygen content using a Hersch cell.

This investigation was begun in 1965 and it was hoped to extend it by using more intense pulses from a new linear accelerator. This had, however, to be postponed because of a delay in the commissioning of the accelerator.

### Suppression of Natural Haemolysin Titre in Rabbits exposed Daily to Gamma Radiation

ACUTE whole body X-irradiation of rabbits with 300–700 r. depresses the synthesis of natural anti-sheep (anti-Forssman) haemolysin<sup>1,2</sup>. This serum antibody, which occurs normally, is thought to arise in response to small amounts of related Forssman antigens entering from the rabbit's environment<sup>3</sup>. Recovery begins about 2 weeks after irradiation and normal or enhanced haemolysin titres are usually reached in a few more weeks<sup>2,4</sup>. A second irradiation provokes a second sequence of depression and recovery<sup>4</sup>. This resilience following acute irradiations prompted a study of the extent to which haemolysin production could withstand injury sustained during protracted irradiation with small daily exposures.

Of the twenty-four New Zealand rabbits irradiated, eleven had received an injection of sheep red cells 1 yr before, but the other thirteen had not. The control group comprised thirty-eight non-irradiated rabbits of similar ages and backgrounds. Based on LiF dosimetry, the daily midline air exposure to the cobalt-60 gamma radiation averaged 25 r. delivered at a rate of about 12 r./min. The positions of the rabbits in the radiation field were rearranged daily so that each rabbit received the same total exposure every 24 days. All sera, obtained weekly from each rabbit, were titrated for haemolysin by a microtechnique<sup>5</sup> and some also by a photocolourimetric assay<sup>6</sup>. Titre is given as the  $\log_2$  of the greatest dilution of serum yielding at least 50 per cent haemolysis. All pre-irradiation titres were typical of normal rabbits. Avidity determinations<sup>7</sup> and the slopes of the photocolourimetric titration plots<sup>8</sup> suggested, but did not prove, that the haemolysin present in the previously immunized rabbits was natural haemolysin arising from environmental antigenic stimuli.

Although haemolysin titre usually declined with increasing total exposure, it fell more slowly in the previously immunized rabbits (sub-group A) than in those not previously immunized (sub-group B). Thus in A geometric mean titre declined gradually to 30 per cent of the initial level by 5,000 r.; whereas in B, mean titre decreased abruptly after 1,500 r. to a plateau at 10 per cent of the initial titre (Fig. 1). Titres in six rabbits in sub-group B, but none in A, decreased to less than detect-

Fig. 1. Mean  $\log_2$  haemolysin titres in gamma irradiated rabbits (25 r./day) previously immunized (triangles) or not previously immunized (circles) with sheep erythrocytes. Squares, unirradiated controls; open symbols, photocolorimetric assay; closed symbols, microtechnique; †, animal deaths.

able levels (although in one antibody reappeared and its titre increased gradually thereafter). Some animals in both sub-groups maintained near-normal titres. The degree of depression was usually independent of initial titre.

Body weight remained fairly constant in eighteen out of twenty-four rabbits which survived 5,000 r. In a separate experiment, the blood lymphocyte count declined 65 per cent after the first 600 r. and decreased only gradually thereafter. There was no marked granulocytopenia.

Five rabbits (two from sub-group A and three from B) had survived an accumulated exposure to 7,400 r. when they were injected intravenously, together with nine controls, with sheep red cells to test their ability to respond to specific challenge. One rabbit from each irradiated sub-group showed no response; the other three produced  $\log_2$  peak titres of 8.5, 10.5 and 11, which were smaller and occurred later than peak titres of most of the controls (mean:  $12.4 \pm 0.9$ ). These results are consistent with those of previous studies involving protracted irradiation and specific immunization<sup>9,10</sup>.

Natural haemolysin titre is probably maintained by a series of small, independent responses in which the meagre influx of environmental Forssman antigens limits antibody synthesis to a level much below the immunological capacity of the rabbit. This minimal demand, together with cellular repair and replacement during the protracted irradiation, could explain the large total exposures needed to depress haemolysin production.

The relative radio resistance of haemolysin production among the rabbits previously immunized with sheep red cells may reflect either an expanded compartment of immunocompetent cells or, through immunological memory, a greater susceptibility to Forssman stimulus. In either case, survival of a smaller proportion of the relevant cell population might have been enough to maintain the greater titres. It is also possible that some of the haemolysin production persisted from the previous immunization.

I thank Dr R. E. Johnson for the radiation facilities and D. W. Glenn, J. R. Owens and Mrs H. P. Gump for technical assistance.

## PHYSIOLOGY

### Growth of the Foetus

WE have attempted to formulate a generalized mathematical description of the time course of foetal growth, in order to facilitate comparisons of the metabolic stresses of pregnancy in different species. Previous empirical formulae<sup>1-3</sup> have described parabolic relationships between foetal weight ( $W$ ) and gestational age ( $t$ ) of the type  $W = at^b$ , the value of the exponent  $b$  lying between 3 and 4.

The accuracy of these formulae was greatly improved by McDowell and Allen<sup>4</sup>, who pointed out that embryo age should be calculated not from conception but rather from the end of the "lag" phase of prenatal development. The equation then became

$$W = a(t - t')^b \quad (1)$$

where  $t'$  represents the duration of the lag phase. These authors defined  $t'$  as the time at which the primitive streak is first seen. It might equally well be described, however, as the period of time during which the placenta becomes established because the nature of the nutrient supply must after this be profoundly altered.

Exponential growth equations have been suggested, for example, by Weinbach<sup>5</sup> ( $w = A \exp [k(t - t') - A]$ ), and such forms have been regarded as somewhat less empirical in nature because some attempt is made to endow the constants in the equation with a physical significance, either by reference to a "specific growth impulse" of foetal tissue, or simply by appealing to a universal law of compound interest. The limiting factor in the early stages of growth, however, is likely to be the rate of nutrient supply rather than some internal regulatory mechanism. For this reason, it is interesting to discover to what extent foetal growth can be compared with a model in which (1) the gain in weight is decided by the rate at which nutrients are supplied to the foetus across a surface corresponding to the foetal vascular endothelium; (2) the area of that surface remains in constant proportion to the total surface area of the foetus itself, and will therefore be proportional to  $W^{2/3}$ .

If nutrients are supplied at a constant rate per unit surface, the total rate of supply, and hence the rate of weight gain, will also be  $W^{2/3}$ , that is

$$\frac{dw}{dt} \propto W^{2/3}$$

$$\text{Therefore } \frac{dw}{w^{2/3}} \propto dt,$$

which on integration yields the expression

$$W^{1/3} \propto t$$

or

$$W = at^3$$

where  $a$  is a constant, related to the rate of supply of nutrients per unit of surface area.

Allowing for the lag phase  $t'$  the equation becomes

$$W = a(t - t')^3 \quad (2)$$

It is of interest to note that the same "cubic law" has been used by Klein and Revesz<sup>6</sup> to describe the growth of tumours. In this case also, after an initial lag period, the growth of a mass of tissue cells is controlled by the rate of transport of nutrients across its surface.

To test this relationship, a series of weights of foetuses at different gestational ages for a variety of species was taken from Needham<sup>7</sup>. A Fortran programme was written which used a simple iterative procedure to determine the constants  $a$ ,  $b$  and  $t'$  in equation (2) for each species. (The programme was run on the 'Atlas' computer at the University of London Institute of Computer Science.) The best values of these constants were taken to be those which gave a minimum value for the sum of the squared percentage deviations of observed from predicted weights. Table 1 shows the values obtained by this means. The magnitude of the exponent  $b$  was uniformly close to 3.0 in species the birth weights of which ranged from 0.0014 to 16 kg, and which included the slower growing foetuses of primates.

In Table 1, the values of  $a$  and  $t'$  are those which give the best possible fit to the data when a free choice of

Table 1. CONSTANTS IN THE GROWTH EQUATION  $W = a(t - t')^b$  FOR THE FOETUSES OF SEVERAL SPECIES

Species	$a \times 10^4$	$t'$	$b$
Chick ( <i>Gallus domesticus</i> )	2.6	1.0	3.2
Mouse ( <i>Mus musculus</i> )	1.0	8.0	3.0
Guinea-pig ( <i>Cavia porcellus</i> )	0.6	15.0	3.0
Pig ( <i>Sus scrofa</i> )	0.9	19.0	2.9
Cow ( <i>Bos taurus</i> )	15.0	58.0	2.7
Rhesus ( <i>Macaca mulatta</i> )	5.0	35.0	2.4
Man ( <i>Homo sapiens</i> )	7.0	41.0	2.7

values for  $b$  is allowed in the programme. Further values for  $a$  and  $t'$ , computed with  $b = 3.0$ , that is, with the assumption that the growth equation is cubic, give almost as good agreement with the experimental data. This is illustrated in Fig. 1, in which curves derived from the cubic equation are plotted with the experimental values. It therefore appears that the foetuses of avian and mammalian species, after an initial lag phase, conform to a cubic law of growth, differences in the size of offspring being determined by the rate of transport of nutrients to the foetus, as illustrated in Fig. 1 by the range of values of  $a$ .

## Blocking of Potassium Currents by Pronase in Perfused Giant Axons

ALTHOUGH there is evidence that axonal membrane potentials are related to sodium and potassium movements<sup>1</sup>, there has been little explicit discussion of how these ion movements may be initiated, or of the chemical processes which may permit them to occur<sup>2</sup>. Because it is not possible to identify the molecules involved by measuring potentials and associated ion movements, there is a need for experiments in which the membrane is modified in a known manner and the effects on potentials and ion movements then studied. The molecular dissection of the axonal membrane by internally applied enzymes<sup>3</sup> has shown that most proteases (trypsin, chymotrypsins and papain) block the action potential and induce a considerable increase in sodium and potassium permeabilities<sup>4-7</sup>.

Experiments reported here suggest that the hydrolytic activity of the enzyme pronase (*Streptomyces griseus* proteinase<sup>8</sup>) modify the protein structure of the axonal membrane and that this alteration causes a partial block of potassium currents without affecting sodium currents.

The experiments were carried out on the giant axon of the Chilean squid, *Dosidicus gigas*. Isolated axon fibres were suspended in a bath of potassium-free artificial sea water at a controlled temperature (430 mmolar sodium chloride, 50 mmolar magnesium chloride, 10 mmolar calcium chloride, 5 mmolar *tris* at pH 7.5). The axons were perfused internally by the suction perfusion procedure described in detail elsewhere<sup>9,10</sup>. A steady perfusion rate of about 100  $\mu$ l./min was obtained and an internal electrode was introduced until its tip was half-way along the perfused axon (average length under perfusion about 2.0 cm). The membrane potential was measured between this point and an external reference electrode. Both internal and reference electrodes were silver-silver chloride-potassium chloride cells. The point

control voltage-clamp system was used to measure the ionic currents<sup>11</sup>. A platinum wire was used to supply current along the part of the axon which was being perfused. The wire was insulated except for the 2.0 cm in the perfused zone, which had been plated with platinum black.

Fibres were perfused externally, in potassium-free artificial sea water, and internally with potassium solution (550 mmolar potassium fluoride, 5 mmolar *tris* at pH 7.3) for about 10 min. Next, the fibres were internally perfused with potassium solution containing inactivated pronase at a concentration of 1 mg/ml. (as a control). This solution was kept inside the fibre for about 10 min (in one case for 20 min). The fibres were then perfused with active pronase (Calbiochem, grade A) at the same concentration added to the potassium solution. After 10–15 min (in one case after 30 min) of perfusion with active pronase fibres were perfused again with potassium solution for 10–60 min.

Resting and action potentials were recorded each minute for each experimental condition. Several voltage-clamp series were also run (at least one voltage-clamp series in each case). During the voltage-runs, the membrane was pulsed from the resting potential (about -55 mV) to a series of depolarizing values up to +80 mV.

**Effect of pronase on potentials and on voltage-clamp currents.** The development of plateau action potentials induced by the pronase perfusing solution is shown in Fig. 1. All fibres treated with active pronase (a total of four fibres) developed plateau action potentials and their resting potentials decreased from an average value of -55 mV to -53 mV. Action potential 1A was recorded 1 min before removal of the inactivated pronase (active pronase solution heated at 90° C for 5 min). Action potentials from 1B to 1H were measured every minute after perfusion with active pronase to show the development of the plateau falling phase. Action potential 1H was recorded 30 min after the removal of the active pronase from the perfusing solution.

It should be pointed out here that earlier experiments<sup>5</sup> indicated to us that protein hydrolysis, and therefore protease action on the axonal membrane, could be prevented either by heating the protease solution or by decreasing the temperature of the sea water of the bath while the active enzyme was inside the fibre. The heated protease control demonstrated that the blocking properties observed were not a result of the presence of low molecular

Fig. 1. Membrane action potentials showing the development of a plateau falling phase. Record A was taken 10 min after the start of internal perfusion with inactivated pronase. Record B represents the spike recorded 2 min after the addition of 1 mg/ml. of active pronase to the perfusing solution. For these two records the time scale was 4 msec. Record C was taken 5 min after the addition of active pronase. Records D, E and F show the slow development of plateau membrane action potentials. Each record was taken every minute. The time scale was 2 msec. Records G and H were taken 8 and 10 min after the addition of the enzyme. The time scale was 4 msec. Record I was taken 15 min after the removal of the active enzyme from the perfusing solution. The time scale was 80 msec. The temperature of the external solution was 16° C.

Fig. 2. Current-voltage relationships showing the effect of pronase on potassium currents. Vertical axis represents voltage clamp currents, either maximum sodium inward currents or steady state potassium outward currents. Horizontal axis represents clamped-membrane potentials in mV. ○, Current-voltage relationships measured after 7 min of the addition of the inactivated pronase. ●, Current-voltage relationships measured 25 min after removal of the active pronase from the perfusing solution. The pulse duration was 45 msec. The temperature of the external solution was 16° C.

weight contaminants. It did not show, however, whether or not the enzyme charge (and not the protein breakdown) was responsible for the blocking of the potentials. The low temperature control, on the other hand, seemed to give a good indication of enzyme effect. When looking for a specific inhibitor of the pronase we found that most of them<sup>12</sup> affect the properties of the axonal membrane when applied internally<sup>13</sup>. Although in these experiments it was not possible to use decreased temperatures to inhibit protease, in one axon, kept at a temperature of 10° C (in all others the temperature was between 15° and 17° C), the latency for developing plateau action potentials was 4 min longer.

Two current-voltage relationships in a typical experiment in which the perfusing solution contained first inactivated then active pronase are shown in Fig. 2. This shows current-voltage relationships during internal perfusion with inactivated pronase and during perfusion with potassium solution about 10 min after removal of the active pronase. The potassium currents for depolarizing pulses from 0–60 mV (-60–0 mV absolute potential) are very small. We have measured the "slope potassium conductance"  $G_K$  at different voltages for the current-voltage relationships given in Fig. 2. Plotting the  $G_K$  values obtained as a function of membrane voltage we found that both curves have essentially the same shape. The  $G_K$  curve measured after treatment with active pronase is displaced about 60 mV along the voltage axis.

These data on four giant axons internally treated with pronase demonstrate that this protease induces a block of the "turning on" of the potassium currents without affecting the sodium currents. As a consequence of this, membrane action potentials developed a plateau falling phase as has been shown before in other experimental situations<sup>14</sup>. Pronase is a very unspecific proteolytic enzyme<sup>8</sup>, and little can be learned about the nature of the peptide links involved in this phenomenon. Our results suggest that either the removal of protein or peptides, and/or the splitting of some proteins, modify the structure of the axonal membrane and that this in turn induces a shift of the  $G_K$  voltage function along the voltage axis. In the latter case the appearance of previously unexposed ionizing groups could modify the charge density

of part of the axonal membrane responsible for the  $G_K$  "turning on", thus shifting the  $G_K$  voltage function along the voltage axis. When protein is removed the remaining structural lipids themselves may generate a high potassium resistance membrane, similar to that observed in artificial protein-lipid membranes<sup>15</sup>.

### Comparison between Tetrodotoxin Effects on Excitation in Mammalian Cardiac Fibres and Squid Giant Axons

BECAUSE tetrodotoxin (TTX) was thought to "selectively" block excitatory inward sodium currents in squid giant axons<sup>1,2</sup>, Dudel *et al.* used TTX as an "independent check" of sodium currents in mammalian Purkinje fibres<sup>3</sup>. Unfortunately, TTX analysis of membrane currents is no longer possible because recent evidence suggests that neither TTX nor the excitation process is specific for sodium.

Excitation of squid giant axons in media free from sodium is not significantly different from excitation in media containing sodium<sup>4-6</sup>. "Heart-like" action potentials with typical spike and plateau phases are observed under many conditions<sup>4-7</sup>, but are characteristic of excitation in external media free from sodium which contain only salts of divalent cations<sup>5,8</sup>. Such action potentials are usually as easily abolished by TTX as those in media containing sodium<sup>5,9</sup>. The presence of sodium is therefore not essential for excitation, and TTX is not specific for any particular ion. It follows that TTX cannot be used to separate the "sodium current" from other ionic currents during excitation.

Because apparently normal excitation takes place in media free from sodium, and because TTX abolishes the inward current regardless of which ions may be carrying that current, a much more general mechanism than a "sodium-specific carrier" or "sodium-specific pore or channel" is required to understand the excitation process. The "macromolecular model" of the excitation process permits such non-specificity of the participating ions, and can thus account for the effects of TTX in both sodium-containing and sodium-free media<sup>9,10</sup>. (Extensive descriptions of the macromolecular model are provided elsewhere<sup>9-11</sup>.)

### Increase of Cerebral Catecholamines caused by 3,4-Dihydroxyphenylalanine after Inhibition of Peripheral Decarboxylase

N-(DL-seryl)-N'-(2,3,4-trihydroxybenzyl)-hydrazine (HCl) (Ro 4-4602) is a strong inhibitor of decarboxylase of aromatic amino-acids *in vivo* and *in vitro*<sup>1,2</sup>. The drug counteracts the increase of 5-hydroxytryptamine which is induced by 5-hydroxytryptophan less markedly in the brain than in extracerebral organs. Small doses of Ro 4-4602 have even seemed to enhance this transformation in the brain; this effect could not be explained<sup>3,4</sup>.

This communication shows that small doses of Ro 4-4602 markedly enhance the increase of cerebral catecholamines induced by 3,4-dihydroxyphenylalanine (DOPA) because of a selective inhibition of extracerebral decarboxylase.

Male Wistar rats weighing 250-280 g, fasted for 16 h, were injected intraperitoneally with 50 mg/kg of Ro 4-4602 and 30 min later with 375  $\gamma$ /rat of DL-2,3-<sup>3</sup>H-DOPA (specific activity 101.2 mc./mmole). Rats given tritiated DOPA alone served as controls. After decapitation at various times following administration of labelled DOPA, blood plasma was deproteinized with perchloric acid, and the brains and hearts were homogenized in the same acid. The supernatants were brought to pH 8.4 and passed through columns of alumina (Woelm, neutral)<sup>5</sup>. Tritiated DOPA and tritiated catecholamines, eluted with 0.2 normal hydrochloric acid and adsorbed on 'Dowex-50 WX-4' in the sodium ion form (200-400 mesh)<sup>6</sup>, were separated by differential elution using 0.1 normal potassium acetate buffer, pH 6, and 2 normal hydrochloric acid, respectively<sup>7</sup>. In other experiments the action of Ro 4-4602 on the activity of decarboxylase in brain and heart of rats was measured. The procedure involved homogenization of tissue in four volumes of 0.05 molar phosphate buffer, pH 7.4, and incubation of the homogenate in Warburg flasks with  $1.5 \times 10^{-5}$  molar DL-DOPA-1-<sup>14</sup>C (specific activity 4.4 mc./mmole) at 37° C for 1 h. The reaction was stopped with 6 normal sulphuric acid, and the labelled carbon dioxide, trapped in the ethanol amine of the centre well, was measured in a liquid scintillation counter after addition of ethyleneglycolmonomethylether. Ro 4-4602 was either injected intraperitoneally 1 h before killing or added to the homogenate. Fig. 1 shows that the ratio of the concentrations of tritiated DOPA in animals treated with Ro 4-4602 versus control animals is increased in brain, blood and heart for at least 4 h. The maximal ratios are 23, 10 and 7.8, respectively. The ratio of the concentration of cerebral tritiated-catecholamines in treated animals versus controls shows a continuous increase up to 58 after 4 h. In the heart, however, the tritiated catecholamine ratio remains considerably less than 1. The measurements of decarboxylase activity made using small amounts of labelled substrate confirm and complete the earlier findings with the manometric method<sup>2</sup>. Accordingly, the decarboxylase activity in the brain of animals injected with Ro 4-4602 is not significantly inhibited ( $P > 0.05$ ) up to 100 mg/kg of the drug, whereas in the heart there is 83 per cent inhibition with 50 mg/kg (Fig. 2).

These results indicate that relatively small doses of Ro 4-4602 (50 mg/kg) cause a selective inhibition of decarboxylase in extracerebral organs like the heart. This probably leads to a diminished formation of tritiated catecholamines and to an increased accumulation of tritiated DOPA in the peripheral tissues. Consequently, the penetration of  $^{14}\text{C}$ -DOPA into the brain seems to increase, and because 50 mg/kg of Ro 4-4602 do not appreciably inhibit cerebral decarboxylase, the formation of tritiated catecholamines in the brain is probably enhanced. Preliminary findings in animals pretreated with 50 mg/kg of Ro 4-4602 indicated that the cerebral tritiated catecholamines increase to 1.4 and 5  $\gamma$ /g 1 h after 16 mg/kg and 150 mg/kg of DOPA, respectively. Thus the catecholamines consist mainly of dopamine (about 80 per cent to 90 per cent) and to a smaller part of norepinephrine (about 10 per cent to 20 per cent). Preferential inhibition of extracerebral decarboxylase might also explain the unexpected enhancement of the DOPA-induced accumula-

Fig. 1. Ratio of tritiated DOPA and tritiated catecholamines in treated versus control rats. Each control was injected intraperitoneally with 375  $\gamma$  of tritiated DOPA alone; the treated animals were administered 50 mg/kg of Ro 4-4602 intraperitoneally followed by 375  $\gamma$  of tritiated DOPA by the same route after 30 min. The points represent averages of three to five experiments  $\pm$  standard error.

Fig. 2. Inhibition of decarboxylase of aromatic amino-acids in brain and heart of rats 1 h after intraperitoneal injection of Ro 4-4602. Total homogenates (2 ml.) were incubated for 1 h with 3  $\mu\text{g}$  of  $^{14}\text{C}$ -DOPA. The points represent averages  $\pm$  standard error of three to five duplicate determinations of a pool derived from two to five animals.

Fig. 3. Activity of decarboxylase of aromatic amino-acids inhibited by Ro 4-4602 *in vitro* (rats). Total homogenates (2 ml.) were incubated for 1 h with 3  $\mu\text{g}$  of  $^{14}\text{C}$ -DOPA. The points represent averages of four to six determinations  $\pm$  standard error.

tion of cerebral catecholamines reported with another inhibitor of decarboxylase, 3,4-dihydroxy-DL-hydrazino-phenylalanine<sup>8</sup>.

The relatively weak inhibitory effect of intraperitoneal Ro 4-4602 on the cerebral decarboxylase possibly results from poor penetration of this drug into the brain. Thus Ro 4-4602, when added to tissue homogenate, causes the same degree of inhibition of decarboxylase in the brain as in the heart (Fig. 3).

In conclusion, Ro 4-4602, owing to a preferential action on extracerebral decarboxylase, increases the content of tritiated DOPA in the blood and consequently seems to increase the supply of the brain with the amino-acid. This probably leads to a marked accumulation of catecholamines (especially dopamine) in the brain but not in the periphery and may have a beneficial effect in neurological disorders such as Parkinsonism.

### Concurrent Measurement of Renin and Angiotensin in the Circulation of the Dog

It has been known for many years that, following a large haemorrhage, dog plasma develops the ability to stimulate smooth muscle *in vitro*<sup>1,2</sup> and to increase the blood pressure when injected into anephric dogs<sup>3-6</sup>. These experiments suggested that the concentration of renin and angiotensin in the blood might be increased in such circumstances, and this has been confirmed in more recent studies, which have shown that both the concentration of angiotensin in the blood<sup>7-9</sup> and the concentration of plasma renin<sup>10</sup> are increased after heavy bleeding in the dog.

We report here an extension of this work in which changes in the concentration of plasma renin, the rate of generation of angiotensin and the concentration of angiotensin in the blood were measured concurrently.

Fig. 1. Dog 2. The responses of three blood-bathed tissues to (i) angiotensin infused at 5 ng/min for 5 min into the assay circuit (rate of flow 15 ml/min); (ii) angiotensin intravenously infused at 1.5 µg/min for 9 min into whole dog; (iii) 580 ml. bled from artery for 5.5 min; (iv) return of shed blood over 2 min. The tissues were a rat stomach strip (R.S.S.) and two rat colons (R.C.), the lower of which was treated with propranolol. The record of arterial blood pressure is also included.

Anaesthesia was induced with ether or halothane and maintained with chloralose and pentobarbitone as in previous experiments<sup>8,9</sup>. The dogs were respired mechanically and given intravenous heparin (1,000 i.u./kg).

The concentration of renin was measured in arterial plasma after an extraction procedure which eliminates detectable endogenous substrate, angiotensinases and accelerators and inhibitors of the renin/substrate reaction. Replicate estimates using this method vary with a standard deviation of 11.8 per cent<sup>11,12</sup>.

The concentration of angiotensin in arterial blood was estimated by the "blood-bathed organ" superfusion technique<sup>13,14</sup>. Changes of angiotensin from the initial concentration were measured, because the absolute concentration can only be derived from the fall in the tissue baseline occurring after bilateral nephrectomy<sup>9</sup>. The response of the assay organs was calibrated either in terms of the concentration of angiotensin in the blood by infusing angiotensin (synthetic asp<sup>1</sup>-NH<sub>2</sub> val<sup>5</sup> octapeptide, CIBA) at a known rate into the blood passing over the assay organs; or in terms of the rate of generation of angiotensin by intravenously infusing angiotensin at a

Fig. 2. Dog 6. The changes in the concentration of plasma renin and the rate of generation of angiotensin associated with arterial bleeds of 630 ml., the return of the blood, and the inflation of an aortic balloon just above the renal arteries to reduce renal arterial pressure. (Angiotensin, closed columns; renin, open columns.)

known rate (Fig. 1). The possibility that this method may overestimate the rate of generation of angiotensin by up to 10 per cent is discussed elsewhere<sup>15</sup>. The superfusion assay method itself also has a random error of similar size.

The experimental stimuli used, as in previous studies<sup>8-10</sup>, were: (a) bleeding from an artery; (b) expansion of the blood volume; (c) marked reduction in renal arterial pressure by inflation of a balloon in the aorta just above the origins of the renal arteries.

The results in the eight dog studies are summarized in Table 1, and are shown graphically in Fig. 2 for the most prolonged experiment (dog 6). In general, there was good correlation between changes in the concentration of rennin, the rate of generation of angiotensin and the concentration of angiotensin in the blood.

Occasional divergences were encountered. Thus in dog 1 an increase in concentration of plasma rennin from 43 U/l. in sample 3 to 75 U/l. in sample 4 was not accompanied by a detectable change in angiotensin. Another discrepancy occurred between the third and fourth samples from dog 8, where the rate of generation of angiotensin increased while rennin fell slightly. Usually, however, in individual dogs, a given change in the concentration of plasma rennin was accompanied by a roughly constant proportional change in the rate of generation of angiotensin and in the concentration of angiotensin in the blood.

The findings suggest therefore that the acute changes in circulating angiotensin observed in these experiments resulted largely from changes in the concentration of the enzyme rennin in blood. The magnitude of the change in angiotensin, however, could well be subject to other influences, which might vary considerably from one animal to another, but which in individual dogs do not alter acutely. Differences in concentration of substrate, angiotensinase activity, and activators and inhibitors of the rennin/substrate reaction may all be important in determining this difference between individuals.

## Rennin and the Gastric Secretion of Normal Infants

RENNIN is known to be secreted in the fourth stomach of the calf and probably in the stomachs of other young ruminants<sup>1,2</sup>. In the calf it is accompanied by the secretion

Fig. 1. The action of crystalline pepsin (a) and crystalline rennin (b) on human whole casein. 0.1 ml. pepsin or rennin solution was added to 3 ml. 0.1 per cent casein in acetic acid-sodium acetate buffer (pH 5.65;  $I=0.1$ ) at room temperature. Added enzyme concentrations (per cent):  $\times$ , 0.1;  $\circ$ , 0.01;  $\bullet$ , 0.001;  $\triangle$ , 0.0001.

of pepsin and the ratio of rennin to pepsin decreases as the calf grows<sup>3,4</sup>. The two enzymes can be distinguished by their different pH optima and by the fact that while both have strong milk-clotting powers the proteolytic activity of rennin is comparatively very slight.

The gastric juice of the human adult contains other proteolytic enzymes besides pepsin but none of these has the milk-clotting power which would be expected of rennin<sup>5-8</sup>. By analogy with the secretory pattern in the calf, however, it is in the gastric juice of infants that rennin secretion in the human might be most hopefully sought. Little work seems to have been published in this field apart from a report by Andersen<sup>9</sup> that the ratio of milk-clotting to proteolytic activity in gastric juice samples taken from infants 2-7 months old was the same as that of adults, a finding which suggests that these babies were not secreting rennin.

I have studied the problem of the secretion of rennin in the stomachs of still younger infants, both premature and full term, using human casein as the substrate for both pepsin and rennin. The age range was from birth to 6 weeks old. Activity was measured by the increase in turbidity caused by either enzyme acting on the substrate at pH 5.65; this property is dependent on the  $\alpha$ -casein fraction of whole human casein and does not require the presence of calcium ions<sup>10</sup> (Fig. 1a and b). A differential analysis was based on the different rates of destruction of the two enzymes in mildly alkaline solution (pH 9) at room temperature; although rennin is itself inactivated at pH values greater than 7.0 (ref. 2 and 11), the present investigation shows that the rate of its inactivation is much slower than that of pepsin (Fig. 2). As a result of preliminary tests a standard time of 15 min was adopted for the alkaline treatment. It was established that rennin could coexist for several hours with pepsin in conditions likely to be met in samples of gastric juice and still be readily detected by the method (Fig. 3), and that the identification of 0.0002 per cent rennin in the presence of a fifty-fold excess of pepsin (0.01 per cent) presented no difficulty.

Samples of gastric juice were aspirated from the stomachs of both fasting and fed infants. The samples were freed

from mucus and particulate matter by centrifuging, and the clear supernatants were decanted and used in the experiments. Initial pH measurements were obtained using a glass electrode which entailed the dilution of samples smaller than 2 ml. In nearly every sample examined the initial pH was less than 5, and because Foltmann<sup>2</sup> has shown that rennin is rapidly formed from prorennin at pH

Fig. 2. The action of crystalline pepsin and crystalline rennin on human whole casein before and after adjusting the enzyme solutions to pH 9. The treatment with alkali was stopped at different time intervals by adding aliquots of the enzyme solutions to equal volumes of acetic acid-sodium acetate buffer (pH 5.65;  $I=0.1$ ). Turbidimetry measurements were carried out in the conditions given in Fig. 1. The concentration of added enzyme was 0.001 per cent in all experiments. Duration of alkali treatment: pepsin (---),  $\times$ , 0 min;  $\Delta$ , 10 min; rennin (—),  $\circ$ , 0 min;  $\bullet$ , 20 min;  $\bullet$ , 60 min.

Fig. 3. The action of crystalline pepsin and crystalline rennin on human whole casein; conditions as in Figs. 1 and 2. Solutions were stored overnight at pH 5.65 and room temperature before testing. Pepsin 0.001 per cent (---),  $\times$ , before alkali treatment;  $\Delta$ , after alkali treatment (pH 9; 15 min). Pepsin 0.0005 per cent plus rennin 0.0005 per cent (—),  $\circ$ , before alkali treatment;  $\bullet$ , after alkali treatment (pH 9; 15 min).

Fig. 4. Turbidimetry response to a gastric juice sample. ---, Native sample;  $\times$ , before alkali treatment;  $\Delta$ , after alkali treatment (pH 9; 15 min). —, Sample plus rennin (final concentration of rennin 0.001 per cent);  $\circ$ , before alkali treatment;  $\bullet$ , after alkali treatment (pH 9; 15 min).

values below 5, this conversion may be judged to have been favoured in the samples reported here.

In no sample was any evidence found for the presence of rennin. Treatment with alkali invariably led to the complete annulment of the turbidimetry response.

The possibility that rennin, although able to coexist with pepsin in pure solution, might be more rapidly destroyed in gastric juice, was tested by adding known amounts of rennin to samples of gastric juice (Fig. 4). Rennin activity was satisfactorily demonstrated, although losses were rather greater than those encountered in pure solution. It was apparent, however, that the accelerated destruction did not invalidate the method and very low concentrations of added rennin ( $<0.001$  per cent) could still be detected with ease.

Results confirming the absence of rennin from gastric secretions of infants were obtained by an alternative method in which the increase in turbidity in casein solutions at pH 7.2 in the presence of calcium ions was used as an index of rennin activity. Under these conditions pepsin is inactive. In practice the method proved less reliable and less sensitive than that which depends on the destruction of pepsin at pH 9; it was not suitable for the detection of rennin in amounts  $<0.01$  per cent.

Twenty-two samples were examined: sixteen by the method of treatment with alkali (seven from full-term and nine from premature babies; age range at sampling, 0–31 days); six by turbidimetry at pH 7.2 (one full-term and five from premature babies; age range at sampling, 0–43 days). No rennin activity was detected in any sample. Non-rennetic activity expressed in terms of pure pepsin, and uncorrected for the dilution by milk in the case of fed infants, ranged from nil (three samples) to about 0.005 per cent. The mean value for thirty-three samples of gastric juice from human adults recently examined by Texter *et al.*<sup>12</sup> was 0.084 per cent.

I thank Dr J. A. Dodge of the Department of Child Health, Queen's University of Belfast, for help in obtaining samples of gastric juice.

### Diurnal Cycle in Serum Concentrations of Follicle-stimulating Hormone in Men

A DIURNAL rhythm in the activity of human follicle-stimulating hormone (FSH) has been recognized by the use of a sensitive and specific radioimmunoassay technique<sup>1</sup>.

In one study we used twenty-three healthy men, aged from 22 to 38 yr. Venous blood (provided by courtesy of Dr George G. Jackson of the Department of Medicine, University of Illinois) was collected on 2 successive days at 5.30 a.m., when each subject was awakened from sleep, and at 2.30 p.m. The subjects for the second study were three healthy hospital interns (24–27 yr) carrying out normal hospital routines. One doctor (K. A.) slept from 1 a.m. to 6 a.m. and his colleagues from 3 a.m. to 6 a.m. Samples were collected at intervals of 4 h throughout the day, and all subjects were awakened for sampling at 5 a.m. All blood samples were allowed to clot and were then centrifuged. Sera were stored at  $-20^{\circ}\text{C}$ . Samples of 0.5 ml. were analysed in duplicate.

Fig. 1. Variation in serum concentrations of FSH during 24 h.

The results are expressed in mU/ml. of serum (1 U equals the activity in 1 mg of the S1 ovine standard for FSH from the National Institutes of Health, Endocrine Study Section, Bethesda, Maryland). Forty-five pairs of sera from the twenty-three subjects were studied (specimens of one day from one subject were lost). The mean concentrations at 5.30 a.m. were  $0.201 \pm 0.016$  (standard error) and at 2.30 p.m. were  $0.146 \pm 0.018$ , with the overall mean being  $0.174 \pm 0.012$ . The mean error of duplicate determinations was  $\pm 11.1$  per cent. Thirty of the forty-five pairs of sera were greater in the morning, six showed no change and nine were greater in the afternoon. The difference between morning and afternoon concentrations was statistically significant (*t* test for paired data:  $P < 0.05$ ). There were no significant differences in the concentrations at comparable time periods of the 2 days of the study.

The results of the study of the three subjects with multiple samplings during 24 h are shown in Fig. 1. It

can be seen that the concentrations were greatest in the early morning, near 5 a.m., and that they decreased between noon and 4 p.m. These data were examined for the presence of a diurnal cycle by an analysis of variance technique as previously described<sup>2</sup>. The results were very significant ( $P < 0.001$ ). No diurnal cycle was seen in concentrations of luteinizing hormone (LH) measured by a specific radioimmunoassay for human LH similar to the one used for FSH (in preparation).

The timing and amplitude of this FSH cycle resembles that in plasma testosterone<sup>3</sup> and also the well known rhythm in serum concentration of adrenocorticotrophic hormone<sup>4</sup>, but the possible causal connexions among these rhythms are unknown.

The finding of a diurnal cycle in serum concentrations of FSH in men can be added to an already growing list of physiological phenomena showing a diurnal rhythm<sup>2,5</sup>.

### Carbon Dioxide Laser Hazards to the Eye

LASER radiation in the infra-red, for example from a carbon dioxide laser, is heavily absorbed in the surface layer of any biological tissue. The laser beam interacts strongly with tissue to produce heat, and thermal lesions can easily occur in the bare skin on the hands and the face. Protective reflex mechanisms will prevent long accidental exposures of the skin to a continuous infra-red laser, as they do to any other source of heat.

In the eye carbon dioxide laser radiation is absorbed by the cornea. The corneal blink reflex, released after a latent period of 80 msec, acts to close the eyelids, but it is slow enough to make even low power carbon dioxide lasers dangerous to the eye. Heat coagulation causes irreversible damage to the cornea which can impair vision. Because the infra-red radiation has a very small penetration depth, the damage will be localized chiefly in the surface layers of the cornea. This is also true of damage caused by ultra-violet radiation, which is also heavily absorbed by tissues. On the other hand, the outer parts of the eye are transparent to visible and near infra-red radiation. Laser hazards with such radiation are connected with the focusing properties of the optical system of the eye, and the retina may be damaged.

We have studied eye hazards from carbon dioxide laser radiation ( $\lambda = 10.6 \mu\text{m}$ ) in rabbits. A conventional laboratory model carbon dioxide-nitrogen-helium laser with a maximum single mode power of 4 W was the source. A rabbit was placed about 3 m from the laser exit mirror, and a beam splitter and calibrated bolometer monitored the beam power. The absolute power/unit area at the position of the rabbit's eye could be checked calorimetrically between exposures. The measured intensity distribution across the beam is Gaussian, and we used for the power/unit area its average value inside the  $1/e^2$  intensity circle. The average thus defined is 43 per cent of the maximum value. The power level could be varied in steps, through precalibrated damping filters. A calibrated camera shutter set the short

Fig. 1. Energy dose  $Q$  required to release a blink reflex, as a function of exposure time  $t$ .

Fig. 2. The corneal epithelium with coagulation of the cytoplasm of the basal cells and some superficial cells. Stained with haematoxylin and eosin.

exposure times at fixed values, and long exposures were measured with a stop watch.

The corneal blink reflex seemed to respond in a very reproducible way to exposure to the laser radiation, and so we used it as an indication of a heat sensation in the cornea. In one series of experiments, we measured the time interval between the start of an exposure and the occurrence of a blink, at various levels of beam power. In another series, we determined the time required for visible damage, caused by heat coagulation, to appear on the cornea.

The energy dose,  $Q$ , sufficient to release a blink reflex is plotted against exposure time,  $t$ , in Fig. 1. In the range 0.01–5 sec the experimental curve follows the relationship  $Q = k\sqrt{t}$ . This fits a simple thermal model, with heat conduction from the surface as the principal means of loss. The release of a blink reflex then corresponds to a definite increase in the corneal surface temperature. With long exposures, the experimental curve deviates from its theoretical course, and we attributed this to the onset of additional loss mechanisms. At very low levels of power such loss mechanisms will prevent the corneal surface temperature from reaching the value necessary for the release of a blink reflex. In the simplest case we expect at long exposures a  $t$ -rather than a  $\sqrt{t}$ -dependence.

The experimental curve relating damage dose and exposure time has a similar shape, but the threshold level is roughly a factor of two above the blink reflex threshold. For an exposure time of 1 sec the damage will be barely visible if the delivered energy is 0.3 cal/cm<sup>2</sup>.

Histology of the laser irradiated cornea showed some features typical of threshold damage which are shown in Fig. 2.

We conclude that the radiation from carbon dioxide lasers must be considered dangerous to the eye, because even low power radiation may cause irreversible changes in the cornea, which lead to impaired vision. Reflexes from metal surfaces, which have very high reflectivity at 10  $\mu$ m, may be nearly as harmful as the direct beam. Ordinary glasses, with side covers, absorb the radiation and are therefore recommended to all personnel working with these lasers. The blink reflex may offer some protection at very low power levels, but should not be relied on.

### Critical Closing Pressure in Blood Vessels

In considering the control of blood supply to tissues it used to be assumed that the calibre of a blood vessel decreased progressively as tone in the muscle of its wall increased.

In 1951 Burton suggested that, for theoretical physical reasons, there must be a critical level of pressure for each small blood vessel below which the vessel becomes unstable and collapses, thus suddenly closing completely<sup>1</sup>. His concept of critical closing pressure was widely adopted and has been applied in biology and medicine ever since. It is quoted in most larger textbooks of physiology and cardiology throughout the world<sup>2,3</sup>.

Burton thought that the phenomenon explained certain features of shock, of which low blood pressure is characteristic. The concept is fundamental to the understanding of the control of blood supply to vital organs, as well as to the rational management of shock. I therefore wish to point out a fallacy in Burton's logic.

In order that his argument shall stand it is necessary to assume that the muscle in the wall of small blood vessels is able to maintain a constant tension throughout shortening, even beyond the point of zero inert elasticity. But this is not so of muscle in general, and has not been shown to be so in this special case.

Critical closing pressure is therefore not an invariable logical necessity for all small blood vessels, as suggested by Burton. Whether or not it occurs in any particular instance depends on the relation of the Laplacian graph of tension/radius to that of tension/length of relevant muscle. It requires to be demonstrated experimentally in each case.

## PATHOLOGY

## Excretion of Hypoxanthine and Xanthine in a Genetic Disease of Purine Metabolism

In man uric acid can be produced through a number of pathways which ultimately involve the action of xanthine oxidase on hypoxanthine or xanthine. The principal pathway seems to be through xanthine, which could be formed from guanine or xanthylic acid. Evidence for this is the predominance of xanthine over hypoxanthine in the urine of patients with xanthinuria in whom xanthine oxidase is virtually absent<sup>1</sup>, and of patients with gout<sup>2</sup> or neoplastic disease<sup>3</sup> treated with the inhibitor of xanthine oxidase, allopurinol. Fractionation of urinary oxypurines has been carried out in a disorder recently described<sup>4</sup> in which hyperuricaemia is associated with marked cerebral dysfunction and bizarre behaviour. In this condition considerably more hypoxanthine than xanthine was found in the urine. Treatment with allopurinol decreased this ratio but did not result in an excess of xanthine as it did in cases of gout or other conditions, and increasing the dose of allopurinol resulted in increasing ratios of hypoxanthine to xanthine. These data indicate that in patients with this condition uric acid is produced directly from inosinic acid.

Patients with this disorder are characteristically mentally retarded, with athetoid cerebral palsy, and are prone to self-mutilation, usually by biting the lips and hands. They have consistent hyperuricaemia and markedly increased urinary excretion and turnover of uric acid in the urine. Rates of conversion of glycine- $U^{14}C$  into urinary uric acid are about 200 times those of control individuals<sup>4</sup>. Genetic transmission is as an X-linked recessive trait<sup>5</sup>.

Allopurinol (4-hydroxypyrazolo(3,4-d)pyrimidine) is a potent inhibitor of xanthine oxidase<sup>6</sup>. It is also a substrate, and the product, alloxanthine, is also an inhibitor of the enzyme. In view of experience with allopurinol in hyperuricaemic children, we thought it of interest to investigate the relative proportions of the urinary oxypurines.

Hypoxanthine, xanthine, and allopurinol were determined by a modification of the method of Wyngaarden<sup>7</sup>. Urines collected from subjects on a low purine diet were chromatographed on a  $1 \times 30$  cm column of 'Dowex 50 (AG 50-W X4)'. The purines were eluted with 0.5 normal hydrochloric acid and assayed at 250 m $\mu$ . Alloxanthine was eluted from a  $1 \times 100$  cm column of 'Sephadex G-10' with 0.05 molar sodium phosphate buffer at pH 7.0 and assayed at 260 m $\mu$ . Total oxypurines were also determined by the enzyme method of Jorgensen and Poulsen<sup>8</sup>. Values obtained agreed well with those from the column.

Allopurinol reduced the amounts of uric acid in blood and urine in four hyperuricaemic children and in a control child, similar to findings in adults with gout. At the same time excretion of hypoxanthine and xanthine increased (Table 1). Relatively large amounts of the oxypurines were found in the urine of the hyperuricaemic children before treatment and in each case hypoxanthine was predominant. Molar ratios of hypoxanthine to xanthine

Fig. 1. Effects of increasing doses of allopurinol on the excretion of hypoxanthine and xanthine. The data are the molar ratios of hypoxanthine and xanthine as determined in 24 h urinary excretions. J. J. was a 15 kg boy with the hyperuricaemic syndrome and J. E. was a 15.4 kg control boy with the Cornelia de Lange syndrome.

Fig. 2. Urinary excretion of allopurinol (HPP) and alloxanthine (AX) and changes with increasing dose of allopurinol in subjects J. J. and J. E.

were 4.00, 2.28, 2.27 and 1.56. In the control child and the adult with gout, xanthine excretion exceeded that of hypoxanthine and molar ratios of hypoxanthine to xanthine were 0.89 and 0.34 respectively. With treatment, the excretion of the oxypurines increased ten- to thirty-fold. In each instance there was a proportionately greater increase in the excretion of xanthine, so that the ratio of hypoxanthine to xanthine decreased. In the hyperuricaemic children, these ratios still exceeded 1.0, while in the control child and the adult with gout, they were 0.28 and 0.26.

This is more clearly seen in Fig. 1 which illustrates the effects of different doses of allopurinol. In the hyperuricaemic patient, J. J., the ratio of hypoxanthine to xanthine rose with increasing inhibition of xanthine oxidase. This suggests that some of the xanthine found at smaller doses was formed from hypoxanthine. There was also evidence of hypoxanthine predominance in the serum. For instance, at 800 mg of allopurinol, concentrations of hypoxanthine and xanthine in the serum were 3.08 and 1.37 mg/100 ml. respectively. In the control patient, J. E., the ratio in the urine decreased to 0.1 suggesting that, ordinarily, a principal source of urinary uric acid is xanthine which is not derived from hypoxanthine.

The excretion of allopurinol and alloxanthine is indicated in Fig. 2. With a dose of 200 mg the data for J. J. and J. E. were virtually identical for both compounds, and so was the excretion of allopurinol at a daily dose of 400 mg. Alloxanthine is cleared more slowly by the kidney than allopurinol. With a dose of 800 mg, 91 per cent of

Fig. 3. Effects of allopurinol on the total excretion of uric acid, xanthine and hypoxanthine in the urine. Data for xanthine and hypoxanthine were expressed as mg of uric acid equivalents and the sums of the three purines were plotted at the various doses of allopurinol. Data on additional 24 h urine collections on J. J. confirmed the data graphed at 0, 400, 800 and 1,200 mg. For instance, on 2 separate days on the 1,200 mg dose, the excretion of total oxypurine was 767 and 746 mg/24 h.

the drug in serum was alloxanthine, while in urine only 63 per cent of the total pyrazolopyrimidine was alloxanthine. Levelling off of alloxanthine excretion with larger doses and the linear increase in the excretion of allopurinol with doses greater than 600 mg suggest progressive saturation of xanthine oxidase.

The total excretion of xanthine, hypoxanthine and uric acid decreased progressively with increasing dose in the control J. E. (Fig. 3). A decrease in total excretion was also observed in the adult (Table 1) and has been found regularly in adults in this and other laboratories. This was not true in the hyperuricaemic children. The patient J. J. has excreted more uric acid, but a series of collections for more than a week were in the range of the value charted. When allopurinol was given, excretion of uric acid promptly decreased, but the total excretion of uric acid and the other oxypurines increased.

We conclude that the pathways involved in purine interrelationships in this disease are not the same as those of control individuals or of adults with gout. The data suggest that a principal source of the excessive production of uric acid is hypoxanthine, whereas in others, a large portion of the uric acid produced is formed from xanthine which comes from sources other than hypoxanthine, presumably xanthylic acid and guanine.

The observations are consistent with the recent findings of Seegmiller *et al.*<sup>9</sup> that patients with this disorder lack the enzyme hypoxanthine-guanine phosphoribosyl transferase, which is involved in the re-utilization of purines. If xanthine is not a substrate for this enzyme, absence of the enzyme would lead to an excess of hypoxanthine. In ordinary circumstances most of the purines synthesized might be expected to be used for nucleic acid synthesis, with uric acid excretion reflecting degradation of nucleic acids. The data on controls and on genetic xanthinuria suggest that this leads to xanthine as a principal precursor of uric acid in man. Inosinic acid might be converted to xanthylic acid and then to xanthine, while guanylic acid might be converted to guanine and then to xanthine.

The relationship of these observations to the overproduction of uric acid repeatedly documented in this syndrome is not clear. It seems likely that the overproduction reflects a reduced feedback inhibition, but the feedback inhibitor has not as yet been defined. Decreased total oxypurine excretion in controls after treatment with allopurinol could result from the action of allopurinol as a feedback inhibitor or from re-utilization of oxypurines protected from degradation. Increased incorporation of

hypoxanthine into nucleic acid has been demonstrated by Pomales *et al.*<sup>10</sup> in mice treated with allopurinol. A block in the re-utilization of hypoxanthine might explain a failure to decrease total oxypurine excretion in hyperuricaemic children. There was, however, an increase after treatment with allopurinol. Possibly allopurinol is capable of further reduction of levels of feedback inhibition, or renal clearance of xanthine and hypoxanthine higher than uric acid might lead to excretion in the urine of purine normally excreted in the intestine.

This work has revealed principal differences from the normal condition in the excretion of purines in this syndrome. The elucidation of the mechanisms involved should provide important information on the nature of the mutant individual and could contribute more generally to the understanding of interrelations of purine metabolism in man.

This work was supported by grants from the National Institute of Child Health and Human Development and the General Clinical Research Branch, US National Institutes of Health. We thank Mrs JoAnne Chislett for her expert technical assistance and Drs D. Hoefnagel, William J. Oliver, and Robert E. Carrel for making their patients available for study.

### Production of Phage-neutralizing Activity in vitro by Cells derived from Burkitt's Lymphoma

THE production of antibodies after exposure to antigens *in vitro* has been reported<sup>1-4</sup> to occur with immune competent cells from nonimmunized animals, but antibody production in response to specific antigens does not seem to have been observed with cultured cells of established human lines. We have now exposed cells of the human lymphoblastoid line P3-J ("Jijoye"), taken from patients with Burkitt's lymphoma, to Coliphage T<sub>2</sub> *in vitro*, and have found that the exposed cells appear to produce a factor capable of neutralizing the phage, probably an antibody. Roswell Park Memorial Institute (RPMI) cell lines<sup>5</sup> No. 41 and No. 212, derived from human osteosarcoma and mesothelioma, respectively, produced no such factor.

The P3-J cells were originally provided by R. J. V. Pulvertaft. Cultured cells, packed by centrifugation, were exposed to Coliphage T<sub>2</sub>; the ratio of cell population to number of plaque-forming units ranged from 1:50 to 1:100. After incubation with T<sub>2</sub>, the cells were washed five times to remove unadsorbed T<sub>2</sub> and were resuspended in spinner flasks containing RPMI medium 1640, a modification of McCoy's medium, supplemented with 20 per cent foetal calf serum and including 100 u/ml. of penicillin. The cell population was maintained at 8-15 × 10<sup>5</sup> cells/ml. by the addition of fresh medium. On the fifth and sixth

days of incubation, the medium was collected and was centrifuged for 2 h at 35,000g. Protein isolates were prepared from the supernatants by addition of sufficient saturated ammonium sulphate solution to provide a final concentration 40 per cent of saturation followed by dialysis. The final volume of every preparation was 1/20 of the original volume of the culture medium.

To assay phage inactivation, 1 ml. samples of protein fractions were each mixed with 1 ml. of fluid containing 500 P.F.U. of  $T_2$  and were incubated for 1 h at 37°C. Plaque counts were determined by the agar layer method and controls were set up with similar preparations obtained from fresh medium and from the medium in which P3-J cells not exposed to  $T_2$  had been cultured. Similar experiments were carried out with cell lines of non-leukaemic origin, RPMI No. 41 and No. 212.

Inactivation of  $T_2$  was expressed as the percentage reduction in the number of plaques formed in experimental samples as compared with control samples. In all experiments summarized in Table 1, the number of plaques was reduced in samples containing  $T_2$  mixed with protein fractions isolated from the culture medium in which P3-J cells previously exposed to  $T_2$  had been cultured.

CR, Cleland's reagent.

\* Effect =  $\frac{\text{experimental plaque count} - \text{control plaque count}}{\text{control plaque count}} \times 100\%$

† Includes cases in which experimental count is greater (within standard deviation) than control count.

The plaque counts of six to ten plates for each group of experimental samples were compared with the counts of an equal number of plates for controls isolated either from fresh medium or from medium in which cells exposed to  $T_2$  had been cultured. The reduction in numbers of plaques ranged from 5 per cent to 50 per cent, and the value of  $P$  for most experiments was less than 0.05. The standard deviation of the plaque counts for each experimental group was less than 7 per cent, and the plaque counts for the two control groups differed less than 4 per cent.

When the protein isolates were treated with Cleland's reagent<sup>6</sup> at a final concentration of 0.02 molar, followed by iodoacetamide at a final concentration of 0.04 molar, a reduction in plaque counts was not observed. When cells that had been exposed to  $T_2$  were assayed with the unrelated  $T_5$ , there was no significant reduction in plaque counts, indicating the specificity of the reaction.

Evidently the P3-J cells previously exposed to  $T_2$  and grown *in vitro* produced a factor that was capable of inactivating  $T_2$ . The effect was specific, because no effect was observed when the assay was performed with  $T_5$  or when the protein isolates were treated with Cleland's reagent. P3-J cells in culture have been shown<sup>7,8</sup> to produce immunoglobulins. The nonhaematopoietic (or nonlymphopoietic) lines RPMI No. 41 and No. 212 do not produce immunoglobulins, and medium in which cells of these two

lines had been cultured did not show any inactivating effect on  $T_2$  when the cells were exposed to  $T_2$  and cultured. These results strongly suggest that exposure to  $T_2$  stimulates P3-J cells to produce specific antibodies in culture.

It is not known whether an antigen or RNA from macrophages<sup>1,9</sup> previously exposed to an antigen stimulates the so-called stem cells to divide into cells producing an antibody, or whether it directly stimulates immune responsive cells. In view of the fact that P3-J cells are a mixed population, the present study cannot give any definite answers to the questions raised. Further studies are in progress to characterize the antibody like factor involved and to elucidate the nature of the cells that produce this factor.

## Lysosomes in Malignant Skin Tumours

In the course of a study on the histochemistry of experimentally induced carcinogenesis in mouse skin I observed that a few applications of benzyrene to the skin induced apparent activation of lysosomes in the epidermis<sup>1</sup>. I considered it of interest to examine the state of lysosomes in the final tumour stage, especially in tumours classified as malignant.

Tumours were induced in the skin of mice ( $A_2G$  strain) by weekly paintings with 0.5 ml. of 0.8 per cent solution of benzyrene in liquid paraffin. Tumours began to develop at between 30 and 40 weeks. The skin tumours were diagnosed as malignant when on histological examination the epidermal tumour cell masses had infiltrated into the underlying panniculus carnosus muscle<sup>2</sup>.

Frozen sections of the tumour samples were cut by the "controlled-temperature freeze sectioning method" of Cunningham *et al.*<sup>3</sup>. Acid phosphatase was demonstrated by Holt's modification of the Gomori method<sup>4,5</sup>. In normal mouse skin an incubation time of 20 min in the Gomori medium produced well stained particles in the epidermis. These stained cytoplasmic particles have been shown to possess similar characteristics to the biochemically defined lysosomes<sup>6</sup>. After incubation for 1 h, the intensity of staining for the enzyme was so great as to mask completely the presence of discrete cytoplasmic particles.

In marked contrast, however, the tumour cells showed only a few stained particles even after incubation for 1 h. It was only after incubation for 2 h that a definite reaction was produced in the form of numerous stained particles

with some diffuse cytoplasmic staining. It seemed likely that this resulted from the development of resistance of the lysosomal membrane in the tumour cells. Because benzpyrene is soluble in lipids, it is possible that the carcinogen is absorbed by the lipo-protein membrane of the lysosomes. Repeated applications of the carcinogen may result in a stabilization of the lysosomal membrane with a resultant increase in the resistance and impermeability of the lysosomes as evident in the tumour cells. The release of lysosomal enzymes has been suggested as one of the causes of gradual ageing and death of cells<sup>7</sup>. Tumour cells therefore may be protected from the effects of their own lysosomal enzymes by the intractable nature of the lysosomal membranes, and this could be a contributory factor in the continuous growth of such cells.

I thank Dr J. Chayen for helpful discussion. This work was carried out during the tenure of a grant from the Lilian May Coleman Cancer Research Fund in the Department of Pathology of the Royal College of Surgeons, London.

## CYTOLOGY

### Correlation between Sperm "Redundancy" and Chiasma Frequency

Most male animals produce a large number of spermatozoa, whereas their females produce a relatively small number of eggs. Classically, this has been related to dilution problems in the external fertilizing medium of the female genital tract, and to synergic effects of super-numerary sperm in dissolving egg membranes or stimulating the female tract. The wide range of sperm redundancy (from 2.0 to  $2 \times 10^{10}$ ), however, suggested that another more immediate cause may be responsible. If a multiple process during spermiogenesis regularly fails in a proportion of attempts, then the number of "perfect" sperm may only be a small proportion of the total, the total produced being related logarithmically to the number of such faulty multiple processes in the production of each sperm. For example, if half such processes are faulty, then it is to be expected that

$$2^P = \frac{R}{n} = r$$

where  $P$  is the number of processes in the production of one sperm,  $r$  is the sperm redundancy,  $R$  is the sperm number divided by the zygote number for one copulation, and  $n$  is the (small) number of "perfect" sperm still required for each egg to meet the exigencies of random collision paths. It was found (Fig. 1) that for those few organisms for which both chiasma frequency and sperm redundancy have been investigated, a logarithmic correlation of the form

$$1.5C = \frac{R}{40}$$

Fig. 1. Sperm number/zygote number and mean chiasma frequency for the species for which both figures have been published. *a*, *Drosophila*; *b*, *Apis*; *c*, *Schistocerca* (preliminary results on sperm number by Miss Judy Kemp); *d*, Chinese hamster (calculated from *f*, on the assumption that the sperm weight is the same and that the proportion from vas deferens is the same); *e*, mouse; *f*, golden hamster; *g*, pig-tailed macaque (chiasma frequency, Egovque unpublished); *h*, man; *j*, bull. Note: Correlation coefficient for chromosome number ( $n$ ) and  $R$  for thirty-nine species is 0.62. Correlation coefficient for DNA/haploid nucleus and  $R$  for thirteen species is 0.12.

fits the points well. This may be taken to imply that about one in three chiasmata has a result which renders the resultant sperm less than "perfect".

Genetic evidence for exactly corresponding breaks and joins in the homologous chromatids is all derived from successful gametes, and leaves open the possibility that failed gametes may have had some inexact chiasmata. Lewis and John<sup>1</sup> made the point that linear exactitude is rare in such biological systems; furthermore, Whitehouse's suggestion<sup>2</sup> that hybrid DNA may initially be formed at chiasmata leads to a theoretical expectation of exactness in only half the resultant reconstituted segments; the others might have an interpolation or deletion of a few nucleotides. He complicates his theory to rectify this.

Implications of this idea are many. Eggs would also be expected to show similar redundancy, and this may therefore be the basis of oocyte atresia in mammals, and in general the production of only a few eggs from large numbers of oocytes by those forms with a large investment (for example, yolk) in each egg. Internal fertilization would then be primarily an opportunity for sperm selection, so that only "perfect" gametes are offered at fertilization. Organisms with large numbers of zygotes in each generation (for example, oysters, plaice) might be expected to show less selection and so to produce a much wider genetic spectrum of zygotes than adults; only a few could survive in normal conditions, but changed environment might result in saltatory evolution. This hypothesis may also have implications for basal mutation rate, the selective value of male haploidy and fertility studies. Notably, gynogamones and other gynogenetic substances which agglutinate sperms may be selective rather than trapping devices.

Preliminary experimental results are promising; investigation of the number of sperms in locust (*Schistocerca*) spermatophore shows it to be of the order of  $2-3 \times 10^5$ . This correlates perfectly with chiasma frequencies of 18-20, assuming 100 zygotes to result. Further work on other organisms, and on sperm competition in mammals, is in progress. Information about sperm number

or chiasma frequency in a variety of organisms is being sought and information will be welcome.

### Establishment of an Insect Cell Strain persistently infected with an Insect Virus

INSECT tissue culture has received particular attention in the fields of virology, cytology, genetics, developmental biology and insecticide research. The first insect cell line was established by Grace<sup>1</sup> from the ovarian tissues of *Antheraea eucalypti*, and two others were reported to have been established from *Aedes aegypti*<sup>2</sup> and *Drosophila melanogaster*<sup>3</sup>. This article reports the establishment of a cell strain, which has been persistently infected with *Chilo* iridescent virus (CIV), from the haemocytes of the rice stem borer, *Chilo suppressalis* Walker (Lepidoptera, Pyralidae).

The first attempt to cultivate insect haemocytes *in vitro* was made by Glaser<sup>4</sup>, but no one has ever succeeded in cultivating insect haemocytes for long periods or in sub-culturing them. In January 1965 several primary cultures of haemocytes were set up from *C. suppressalis* larvae. A modified sitting drop culture method involving cover glasses and microslide rings<sup>5</sup> was used for the primary cultures. The haemocytes were obtained from diapausing larvae of *C. suppressalis* which were reared on an artificial diet in aseptic conditions. The blood which oozed from a puncture made on a proleg of a larva was allowed to drop on to a Ringer-Tyrode salt solution placed on the bottom of the culture vessel. Most of the haemocytes settled on the bottom of the culture vessel within 10 min and were washed by changing the solution six times. Finally, the solution was replaced by culture medium.

The culture medium (CSM-2F) used consisted of 50 mg of  $\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$ ; 120 mg of  $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ ; 160 mg of  $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ ; 120 mg of KCl; 40 mg of  $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ ; 80 mg of glucose; 80 mg of fructose; 520 mg of lactalbumin hydrolysate; 520 mg of Bacto-peptone; 40 mg of choline chloride; 200 mg of TC-yeastolate; 20 ml. of TC-199 medium; 20 ml. of foetal bovine serum; 10 mg of dihydrostreptomycin sulphate; and distilled water added to make the volume 100 ml. The pH was adjusted to 6.2 with potassium hydroxide.

Of the seven different types of cells which constitute haemocytes of *C. suppressalis*, prohaemocytes and plasmatocytes multiplied gradually in the primary cultures. The details of the cell growth in the primary cultures have been reported elsewhere<sup>6</sup>. In most of the primary cultures haemocytes began to degenerate within a month, but continuous cell growth was obtained in one culture, and in this culture the cells began to multiply rapidly 6 months after the culture had been set up.

The first sub-culture was made in July 1965 by taking a part of the growing cell colonies. The primary culture, from which the sub-culture was made, recovered its cell population, and so sub-cultures were repeated more than twenty times from the same primary culture at irregular intervals.

Most of the secondary cultures failed to grow continuously, but some grew very well, and serial sub-cultures were made successfully from one of the secondary cultures. The intervals of serial sub-cultures were more than 20 days during the first 3 months, but were decreased to 10–14 days after December 1965. With the advance of

Fig. 1. Cells multiplied from haemocytes of *Chilo suppressalis*. From a culture 27 months old. Bright phase contrast. ( $\times 120$ .)

Fig. 2. A highly magnified phase contrast photomicrograph of the cells shown in Fig. 1. Arrow indicates a cell undergoing mitosis (anaphase). ( $\times 480$ .)

generations, prohaemocytes became predominant, and plasmatocytes gradually disappeared. The cells began to multiply rapidly and I tried to transfer the cells into Carrel flasks, square bottles, T-flasks or culture tubes of various sizes, from small to large containers.

In March 1966 all cultures were accidentally infected with CIV. Experiments with CIV were being carried out in the same laboratory at that time, and CIV is known to be a stable virus, so that the infection may have been caused by accidental contamination of CIV in the culture medium, although care was always taken to avoid contamination. The infected cells were usually granulated and aggregated to form cell masses, which showed typical iridescence by reflected light<sup>7</sup>, and finally degenerated. Most of the cultures were lost through this contamination, but one culture survived. In this some cells still continued to multiply, although most of them degenerated and debris of dead cells was abundant in the medium.

Seven months after infection with CIV, in October 1966, the surviving cells began to multiply again. Sub-cultures were made at 1–2 week intervals, and a cell strain was established. These cells were probably prohaemocytes. In cell strain culture spherical cells,  $18\text{--}2\mu$  in diameter, were predominant, but there were also a few spindle shaped cells  $34\text{--}1\mu$  long (Figs. 1 and 2). In single cell culture some spindle shaped cells became spherical. When the cells were actively multiplying, they became separated from each other, and suspended in the culture medium or lightly attached to the glass. The cells often aggregated to form cell masses when they were overpopulated. If the cells were cultivated by a rotation culture method they attached themselves to the glass surface firmly and took on a very flat form. This transformation of cells resulted in their degeneration.

The degree of cell multiplication was determined by a replicate tissue culture method used on the cells recovered from CIV infection. Samples (1.5 ml.) of the cell suspension were distributed into 15 x 150 mm roller tubes slanted about 5° from the horizontal and stationary culture was carried out at 25° C. The number of cells were determined with a haemocytometer. The average of values obtained from three tubes was taken as the cell number. A growth curve of the cell is shown in Fig. 3. The mean generation time of the cells was estimated as 4.5 days at 25° C.

As well as actively multiplying cells, hypertrophied and granulated cells, small cell masses and debris of dead cells were always present in the culture. The multiplying cells did not show iridescence, but small crystals which showed brilliant greenish or bluish iridescence were often seen in hypertrophied cells and in debris of dead cells when viewed by reflected light by means of the 'Ultropak'. Small cell masses as a whole sometimes showed iridescence. Ultra-thin sections of hypertrophied cells or cells in small cell masses revealed the presence of many virus particles in crystalline arrangement in the cytoplasm (Fig. 4). In addition to the fully developed virus particles, some empty membranes were seen, and these may be a premature stage of virus particles as Smith<sup>8</sup> suggested in TIV.

Ten months after CIV infection, in January 1967, the cells, the cell homogenate or the cell free culture medium were inoculated into the haemocoel of healthy *C. suppressalis* larvae, and all the inoculated larvae became infected. This suggested that CIV also multiplied in the culture of the cell strain.

When the cells in cultures were fixed with Carnoy's fluid and stained by Feulgen's technique, Feulgen positive materials were rarely found in the cytoplasm of the small spherical cells, while some parts of the cytoplasm of hypertrophied cells and the aggregated cells were Feulgen positive. I therefore assume that the actively multiplying cells are not infected with CIV and that they become infected when the culture conditions change unfavourably for the cells, or they carry a latent infection, in which CIV exists in these cells in the Feulgen negative form and is activated when cell growth becomes unfavourable. This was supported by the fact that iridescence was not observed in the new sub-cultures, but many iridescent crystals were seen in the same cultures when they were kept for a long time without a change of medium.

Fig. 3. A growth curve of cells in the CIV carrier culture, 27 months after the primary culture was set up (forty-two transfers). Medium CSM-2F. Temperature 25° C.

Fig. 4. An ultra-thin section of the cultivated cells infected with CIV, showing virus particles in crystalline arrangement. Empty membranes are also seen. (× 5,000.)

This carrier culture may be used for mass production of CIV, if CIV is used for the microbial control of some insects. It is also possible that the carrier culture can be used for the screening of antiviral agents, because bio-assay of CIV can be carried out easily by injecting the virus into the susceptible insects.

Attempts to eliminate CIV from the cell strain and to establish another virus free cell strain from the primary cultures of haemocytes of *C. suppressalis* are in progress.

## GENETICS

### Mutable Genes in the Light of Callan's Hypothesis of Serially Repeated Gene Copies

MUTABLE genes have been intensively studied in maize by McLintock<sup>1-3</sup> and Brink<sup>4-6</sup> and they occur widely in higher plants<sup>7</sup>. Among many features of mutable genes, all difficult to explain by conventional mutation theory, the following are especially relevant to the present discussion. (a) One original labile gene often gives rise with high frequency to a whole range of more or less

stable alleles, quantitatively graded in their expression. (b) In addition, a labile gene can frequently mutate to other unstable alleles, differing from the original in the timing or frequency of mutation or in the kinds of stable derivatives most often produced. (c) The frequency of mutation is frequently drastically affected by changes of temperature (in several examples higher temperature causes reduced mutation frequency), or by genes elsewhere in the genotype; such variables affect the mutable gene specifically in the sense that they have no evident effect on mutation in general. All these features are well shown in the *pallida-recurvens* mutable system of *Antirrhinum majus*<sup>9,10</sup>. In the following discussion I shall refer to the *Antirrhinum* mutants because I am familiar with them, although McIntock has documented most of the same effects much more thoroughly in maize.

To explain the almost continuously graded variation seen in derivatives of mutable genes Brink<sup>5,6</sup> has proposed that such variation is caused by different numbers of repeated, probably identical self-replicating units associated with the unstable locus. It has not been clear, however, how the repeated units would be integrated into, or attached to, the chromosome, and there is no obvious explanation for the difference between stable and unstable alleles. A recent hypothesis advanced by Callan<sup>10</sup> opens up new lines of thought and suggests explanations for at least some of the properties of mutable genes.

Callan postulates, as a property of some or all genes of higher organisms, a serial (tandem) repetition of DNA sequences; that is to say, each cistron is regarded as being represented by numerous copies joined end to end. The evidence for this model derives from Callan's own studies of lampbrush chromosomes, from Keyl's<sup>11</sup> demonstration of reduplication of DNA within certain polytene chromosome bands in *Chironomus* and from the well-known gross differences in amount of DNA in each genome between related species of animals and plants. Further evidence pointing in the same direction has been provided in the special case of the bobbed locus of *Drosophila melanogaster*<sup>12</sup>.

Serial repetition of gene copies is only consistent with the known facts of mutation and recombination if there is some over-riding mechanism for keeping all the members of the series identical. This problem has been discussed, and solutions proposed, both by Callan<sup>10</sup> and by Whitehouse<sup>13</sup>, the latter dealing with the problem of recombination. Briefly, it is proposed that within each serial gene there is one "master" gene copy (probably at the end) and that the other gene copies in the same series are "slaves" which are corrected as necessary to conform to the master copy. Callan suggests that, at least in the lampbrush chromosomes of oocytes, transcription of DNA into messenger RNA and the correction of slaves by the master both occur as a consequence of the same process—namely, the uncoiling and recoiling whereby all the DNA of a lampbrush chromosome appears to be exposed in turn in the uncoiled lateral loop extending from the chromomere. In the model the slave copies are transcribed into RNA while they are exposed in the loop and, as they are rewound into the chromomere, they are matched in turn with the master gene copy and corrected if they differ from it. The feature of the model which is essential from the point of view of this paper is that transcription and correction are linked. Although transcription and correction need not both occur in all cells (as Callan points out, correction need only occur once in each life cycle) it seems not unreasonable to suggest that certain mutations or structural changes in the master sequence might interfere both with transcription and with correction. The effect of such a change in the master would then be a hereditary loss of activity of the whole series of gene copies, although the slave copies remained non-mutant.

The essential peculiarity of the kind of mutant just postulated would lie in the internal heterozygosity of the mutant gene series; the normal genetic information lost

in the master copy would be retained in the slave copies, though unable to find expression. In the more usual, very stable type of mutant, on the other hand, the correction process would have ensured that all the slaves carried the same mutation as the master.

To explain how an internally heterozygous gene series could be unstable it suffices to show how a defective segment in the master could be removed and replaced by a normal homologous segment derived from one of the slaves. There seem to be several possibilities here, all involving pairing of homologous genetic segments. Such pairing, at least in meiosis and in so far as it is reflected in the frequency of chiasma formation, is known to be sensitive to temperature, with high temperature frequently causing a reduction in pairing. With the notable exception of Brink's<sup>5</sup> phenomenon of paramutation in maize, highly mutable alleles in higher plants are, in general, more or less autonomous, not depending for their mutability on the presence of any particular other allele on the homologous chromosome. Thus any plausible mechanism must involve intra-chromosomal rather than inter-chromosomal interactions. One obvious possible mechanism is unequal sister-strand crossing-over which, following pairing between the defective master on one chromatid and one of the slaves on the sister, could generate a shortened sequence with a normal master on one chromatid and a longer sequence with a defective master and a defective slave on the other. Of these two products the first should be a stable allele of rather sub-normal (but possibly not perceptibly sub-normal) activity. The second should be an inactive allele, which, if the defective slave segment interfered with transcription, would not be able to mutate in one step to anything approaching full activity. After separation of the sister chromatids and their separate replication in clones of cells the two new alleles should be in adjacent "twinning" sectors. In fact, twinning does not seem to be a usual feature of high mutability. Close examination of mutable *Antirrhinum* petals does reveal some possible examples of twinned sectors, but it is difficult to be sure that these are more frequent than could be accounted for by coincident independent mutations; it is clear, in any case, that most fully pigmented mutant sectors are not accompanied by any phenotypically distinct twins. The scarcity of twinned sectors suggests that intra-chromatid rather than sister-chromatid interactions are the more usual cause of mutability. The most obvious possibility is pairing of repeated gene copies on the same chromatid by loop formation, followed by crossing-over as shown in Fig. 1. This could lead to excision of the defective sequence of the master in a closed loop and the generation of a normal master governing a slave series shortened by one (Fig. 1 A(a)) or more (Fig. 1 B(a)) copies, depending on whether the intra-chromatid pairing involved adjacent or non-adjacent copies. Double exchanges within an intra-chromatid loop could result in conservation of the original number of copies but with the shift of the defective former master copy into a slave position one or more positions down the series (Fig. 1 A(b) and B(b)).

Yet another possibility is to invoke the correction process postulated by Callan. One can imagine that the nature of the defect in the master segment is such that it cannot, or only with great difficulty, be imposed on the slave segments, but that fairly frequent correction can occur in the opposite direction—that is to say, from slave to master. Correction of the master segments without crossing-over would lead to the formation of a normally functional gene with the original number of repeated segments (Fig. 2 A(a) B(a)). Rarely, correction might proceed from defective master to normal slave, resulting in a series with the normal number of segments including a defective slave as well as a defective master (Fig. 2 A(b) B(b)). If correction were correlated with crossing-over, as has been postulated to account for some of the features of gene conversion in fungi<sup>14,15</sup>, the new active master

copies might be associated with different numbers of slaves, in the same way as shown in Fig. 1, thus accounting for the quantitative variation between different stable mutant alleles.

An important fact which must be taken into account is that extreme instability of genes is very much the exception rather than the rule. If normal genes are serially repeated they must in general not show crossing-over between different copies in the same series. This suggests that such crossing-over is a side-effect of correction and does not occur, except perhaps rarely, when master and slaves are properly matched. The high stability of normal genes seems a strong reason for preferring correction, rather than crossing-over, as the essential factor in high mutability.

The mechanism just suggested seems capable of explaining virtually all the different kinds of alleles arising at the *Antirrhinum pal* locus. The most common type of mutant, that with stable and full expression of the gene activity, could be caused by correction of the defective master segment with retention of the normal number of slaves. The next most common type, with stable but more or less reduced expression of the gene activity, could be caused by correction of the defective master copy accompanied by crossing-over resulting in a significant shortening of the slave series, assuming the amount of gene product to be more or less proportional to the number of gene copies. Another comparatively frequent type of mutant, similar to the original *pal-recurrens*, but with greatly reduced mutation frequency, could be caused by the duplication of the defect in the master in the most proximal slave copy (Fig. 2 A(b)), thus closing the door to the most common type of mutation (correction, or replacement, of the master by the proximal slave). The duplication of the defect in the master copy in a slave copy some way along the series (Fig. 2 B(b)), where it could block transcription of the more distal copies, might account for mutable alleles (for example *pal-maculosa*, Fincham and Harrison, 1966) able to mutate only to a low level of gene expression. Mutant alleles showing more or less full gene expression, occasionally reverting to the inactive but mutable condition, (Fincham and Harrison, 1966), are more difficult to account for but could be caused by transposition of the defective copy to the far distal end

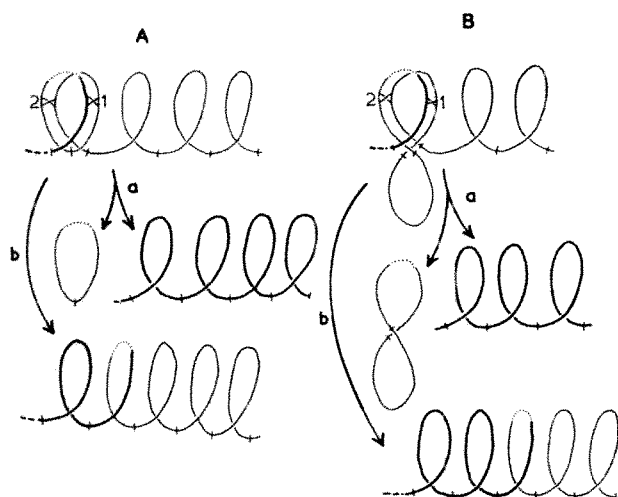

Fig. 1. Possible consequences of intra-chromatid crossing-over. A, pairing of master with first slave segment. (a) Cross-over in position 1 giving excision of defective master copy as a closed loop (lost?) and formation of an active product with somewhat reduced level of activity. (b) Double cross-over in positions 1 and 2 giving product with normal master but defective first slave copy (low level of activity, mutable to higher activity?). B, (less frequent) pairing of master with more distant slave copy. (a) Cross-over in position 1 giving excision of defective master and one or more normal slave copies, and formation of an active product with considerably reduced activity. (b) Double cross-over (positions 1 and 2) giving normal master and defective distant slave copy (intermediate level of activity, mutable to full activity?). Here and in Fig. 2 the thicker lines indicate genetic segments able to be transcribed and thinner lines segments transcription of which is blocked.

Fig. 2. Possible consequences of master-slave and slave-master correction (conversion) without crossing-over. A, pairing of master with first slave copy. (a) Correction of master to conform to slave giving a fully active product. (b) Correction in the opposite direction to give an inactive product with a greatly reduced frequency of mutation to full activity. B, pairing of master with more distant slave copy. (a) Correction of master to conform to slave giving a fully active product. (b) Correction in opposite direction giving mutable product mutating to partial activity only. Association of conversion with crossing-over would give changes in numbers of gene copies in the products as in Fig. 1.

of the series from where it may be occasionally transposed back to the master position.

Additional assumptions would have to be made to account for some other properties of mutable genes in maize which have not so far been mentioned, including infective paramutation<sup>4</sup> and the induction of new mutabilities and the control of existing ones by transposable elements<sup>1-3</sup>. One of the less extravagant extensions of the theory would be to explain transposition in terms of excision of ring elements by intra-strand crossing-over (Fig. 1 B(a)) and their integration elsewhere in the genome by further crossing-over involving regions of partial homology. The analogy with *F* factors in bacteria is suggestive in this context<sup>16</sup>.

Critical evidence bearing on the speculations made in this paper is lacking at present, and various alternative and equally plausible schemes might be devised. It does seem, however, that if Callan's master-slave concept is acceptable on other grounds, it is possible to construct and test a variety of reasonable hypotheses to account for at least some of the properties of mutable genes. A new dimension is also added to our thinking about the relationships between the members of multiple allelic series in higher organisms.

I thank Dr R. Holliday, Mr G. W. P. Dawson and Professor H. G. Callan for reading the manuscript and making helpful comments.

## IMMUNOLOGY

## Distribution of Nephric Antigens in Australian Vertebrates

NOTABLE improvements in immunohistological techniques and the availability of a new fauna prompted us to apply anti-kidney sera previously described<sup>1</sup> to further studies of the species distribution of kidney-specific antigens. We used two sera prepared by immunizing rabbits with microsomal material from human and hamster kidneys respectively, and examined their cross-reactivity with the kidneys of other species by immunofluorescence<sup>2</sup>. Contrary to the earlier reports that cross-reactions are limited to mammals, birds and fish, we found that both sera cross-reacted with all kidneys examined from vertebrates of every class. There was also some cross-reaction with seminal vesicle epithelium in the few species studied.

Kidneys removed immediately after death from mammals (including placentals, marsupials and monotremes), birds, reptiles, amphibians and fish, provided blocks 5 mm<sup>2</sup> × 2 mm thick, which were snap-frozen in a slurry of liquid nitrogen-isopentane at -160° C. Blocks were taken from different parts of kidney and from liver, lung and heart of representatives of each class of vertebrate, and from seminal vesicle, testis, prostate and vas deferens of rat, guinea-pig, cat and dog. They were then sectioned at 6μ in a cryostat at about -20° C either immediately after snap-freezing or after storage for up to 6 months in a sealed container at -70° C. More prolonged storage was associated with a variable loss of antigenicity. Unfixed sections were stained by the immunofluorescence sandwich method with each antiserum followed by goat anti-rabbit-globulin labelled with lissamine rhodamine B (RB 200) or fluorescein isothiocyanate.

The failure to stain sections of organs other than kidney or seminal vesicle provided evidence of specificity of the reaction, and this was further confirmed by persistence of staining of kidney and seminal vesicle by sera which had been repeatedly absorbed with homogenates of liver, spleen, lung and testis from humans or rodents; sheep red cell absorptions of the anti-hamster kidney serum were also used to remove Forssman antibody. Absorptions by similar tissue homogenates from other species were used as required to inhibit non-specific staining of tissue sections of those species. Cross-absorptions with kidney from at least two species of each class of vertebrate and with guinea-pig seminal vesicle were also carried out to study their relative neutralizing effect on the sera.

The species studied and the results of the immunofluorescence staining of the kidneys are summarized in Table 1, from which it is clear that both sera reacted with the kidneys of all the vertebrates examined. Human kidney stained very intensely with the homologous antiserum; the staining of hamster kidney was not checked during this investigation because this rodent is not available in Australia. Kidneys from all the other placental mammals tested stained intensely with both antisera. Kidneys from all the other species stained less intensely with the anti-hamster-kidney serum. The anti-human-kidney serum gave staining of similar intensity with the kidneys of marsupials, monotremes, birds and fresh water fish, and moderate staining of the kidneys of reptiles, amphibians and marine fish. The histological distribution of the staining was almost entirely tubular in all kidneys and glomerular staining was negligible; in the mammals it was brightest in the proximal convoluted tubules.

Seminal vesicle epithelium of rat, guinea-pig, dog and cat was found to stain (Fig. 1) with either antiserum with about half the intensity of the staining of kidney tubules. The staining could be completely inhibited by absorption with kidney or seminal vesicle but the latter was not sufficient to neutralize the capacity of the serum to stain kidney. This indicates that the seminal vesicle antigen was either weakly cross-reacting or, if identical with the

kidney antigen, present in smaller amount than in kidney. The demonstration of such antigenicity in seminal vesicles is not unexpected because, like the fish kidney, it is a mesonephric organ. The sharing of antigenicity between metanephric and mesonephric organs, both kidney and seminal vesicle, indicates that the antigens are not merely a product of organ function but a more fundamental component based in ontogeny.

The anti-kidney sera which had been absorbed by liver, lung and spleen gave no staining with any organs other than kidney or seminal vesicles; there was no staining of testis, epididymis, vas deferens or prostate and absorption with testis did not inhibit staining of kidney or seminal vesicle. The absorptions with kidney homogenates of the various species gave results which were complementary to those in Table 1, in that the homogenates had a serum neutralizing capacity which was roughly proportional to the strength of staining of the corresponding kidney sections. Complete neutralization of the antisera could only be achieved by absorptions with the homogenate of the homologous kidney; similar absorption by kidney preparations of other species inhibited all staining of the kidney of that species and reduced the capacity to stain the kidneys of other species to an extent which varied

Fig. 1. Fresh frozen section of guinea-pig seminal vesicle treated first with rabbit anti-hamster-kidney serum and then with fluorescein-labelled goat anti-rabbit-globulin. Bright fluorescent staining of epithelium. (×250.)

from total inhibition in close relatives to partial inhibition where the relationship was more distant.

It has been suggested<sup>3</sup> that the present antisera contain antibodies to at least two separate antigens, one distributed throughout the nephron and present also in human kidney cancer, and the other largely restricted to the proximal tubules. Absorption of the sera with human kidney cancer homogenates neutralized the first antibody and left the latter with largely undiminished activity. Such cancer-absorbed antisera still stained, though with slightly diminished intensity, the kidneys of vertebrates of all classes and the seminal vesicles. On the other hand, antisera absorbed with marine fish kidney failed to stain human renal cancer sections. This suggests that both the antibodies cross-react between the species and with seminal vesicle; the "proximal tubular antigen" appeared to be the most abundant in both organs.

The disparity between the present findings that some antigens specific for kidney are common to all vertebrates and the earlier results which suggested a less widespread distribution is attributed to improvements in immunohistological techniques, in particular to the use of liquid nitrogen-isopentane slurry for snap-freezing of tissues. This permits excellent preservation of renal architecture and of labile antigens. Those located by the antisera in this study are fairly easily dispersed in the stained sections which must be examined within 30 min of mounting for accurate interpretation.

We thank the Department of Fisheries and Wildlife for help in gathering the specimens, and Miss A. Hühn for technical assistance. The work was supported by grants from the Australian Research Grants Committee and the Anti-Cancer Council of Victoria.

### Antibody Response of Thymectomized Rats after Local Irradiation of the Spleen

THE haemolysin response of rats given a massive dose of X-rays to the surgically exteriorized spleen a few minutes after antigen injection has been found to be essentially normal although delayed for about 2 days<sup>1</sup>. It has also been shown that the antibody response in these conditions can be almost completely prevented either by splenectomy during the latent period or by sub-lethal whole body irradiation within a few hours of the local spleen irradiation<sup>1</sup>. This indicates (a) splenic origin of haemolysin formation and (b) the role of non-splenic lymphoid sites in restoring the antibody response. Histological studies reveal an early repopulation of the locally irradiated spleen by lymphocyte-like cells, followed by the appearance of large pyroninophilic cells and plasma cells<sup>2</sup>. In order to discover the origin of lymphoid cells repopulating the locally irradiated spleen a series of experiments has been performed, and one of them is reported here.

Fig. 1. Mean initial haemolysin response in groups of rats treated as indicated in Table 1. A, Groups 1 (○---○) and 2 (●—●); B, groups 3 (○---○) and 4 (●—●).

Female albino rats were thymectomized at the age of 4 weeks. Three months later one group of the rats was immunized by an intravenous injection of about  $3.5 \times 10^7$  sheep red blood cells and within a few minutes the spleen was surgically exteriorized and locally irradiated with 10,000 R of X-rays<sup>1</sup>. The other group was only immunized and served as thymectomized controls. Two additional control groups of rats of the same age were included: the first was immunized with sheep red blood cells and the second was immunized and locally irradiated as before. Blood samples had been obtained daily for nearly 2 weeks and individual sera were titrated for haemolysins in terms of 50 per cent haemolytic units<sup>1</sup>. At the end of the experiment all thymectomized rats had been autopsied and all those showing macroscopically visible amounts of thymic tissue were rejected. Parameters of the antibody response were individually determined<sup>1</sup> and their means were calculated for each group (Table 1). Average curves of haemolysin titres for each group are shown in Fig. 1.

As shown in Fig. 1A and Table 1, there was no essential difference in the antibody response between rats thymectomized at the age of 1 month and given local irradiation to the spleen 3 months later, and their non-thymectomized controls. This indicates that cells which are responsible for the restitution of the antibody-forming capacity of the heavily irradiated spleen do not come directly from the thymus, and that their response to the antigen localized in the spleen is not dependent on the thymus. This result also suggests that during the first month of life rats are provided with a sufficient number of immunologically competent cells which do not substantially decrease during the next 3 months. This is also supported by the lack of difference in the antibody response between rats thymectomized at the age of 1 month and immunized 3 months later, and their non-thymectomized controls (Fig. 1B and Table 1). In another series, not reported

Table 1. PARAMETERS OF THE HAEMOLYSIN RESPONSE IN RATS AFTER THYMECTOMY AND/OR LOCAL IRRADIATION OF THE SPLEEN

Group	Treatment	Log peak titre	Length in days of		Rate of antibody accumulation	No. of rats

1	Thymectomy at 1 month	3.32 ± 0.26	4.2 ± 0.1	2.0 ± 0.1	5.10 ± 0.50	6
	Antigen + 10,000 R to the spleen at 4 months				3.74 ± 0.36	
2	Antigen + 10,000 R to the spleen at 4 months	3.64 ± 0.17	3.9 ± 0.1	2.1 ± 0.1	5.77 ± 0.53	5
3	Thymectomy at 1 month	3.23 ± 0.27	2.3 ± 0.6	3.3 ± 0.3	3.00 ± 0.55	3
	Antigen at 4 months				4.03 ± 0.19	
4	Antigen at 4 months	3.23 ± 0.16	2.3 ± 0.3	3.4 ± 0.2	2.73 ± 0.20	7
	Antigen at 4 months				2.16 ± 0.17	

All values are means ± standard error.

here, no difference in the antibody response was found between thymectomized and non-thymectomized rats when the interval between thymectomy and immunization was extended to 5 months in similar experimental conditions. All these results are in general agreement with reports<sup>3-5</sup> showing that thymectomy of young or adult animals might result in an impaired immunological responsiveness only several months later.

Local irradiation of the spleen somewhat modified the haemolysin response to sheep red blood cells injected immediately before exposure. When compared with unirradiated controls the antibody response after local irradiation of the spleen was delayed for about 2 days, but normal peak titres were reached during a significantly shorter rise to peak and at a much higher rate of antibody accumulation (Table 1). These results corroborate previous ones, describing the effects of local irradiation of the spleen on the antibody response in rats<sup>1</sup>. On the basis of the present results it could be concluded that in the experimental conditions used the thymus does not seem to play a part in the repopulation of the locally irradiated spleen and in the restitution of its antibody-forming capacity.

### Elimination of Normal Horse IgG labelled with Iodine-131 in Rats receiving Horse Anti-rat Lymphocytic IgG

RECENT reports have indicated that antilymphocytic IgG, in addition to inhibiting the homograft reaction, is capable of suppressing the formation of humoral antibody against a number of antigens<sup>1-4</sup>. Somewhat conflicting results have appeared, however, on the ability of antilymphocytic antibody to suppress the formation of antibody against itself, or against normal IgG globulin obtained from the species in which the antibody was produced<sup>5-7</sup>. We have investigated this problem by studying the effect of prolonged administration of antilymphocytic IgG (horse anti-rat) on the elimination of normal horse IgG, labelled with iodine-131, from rats.

The techniques of raising antilymphocytic serum and preparing purified IgG derivatives have been described previously<sup>3,8</sup>. The labelling with iodine-131 was performed by the method of Hunter and Greenwood<sup>9</sup> and it was found that more than 95 per cent of the radioactivity of the preparation was precipitable with trichloroacetic acid. The rats were females aged 3-4 months (160-210 g) of an inbred hooded strain maintained in this laboratory<sup>10</sup>. Six animals received daily intraperitoneal injections of

Fig. 1. Clearance of normal horse IgG labelled with iodine-131 from the blood stream of rats pretreated with saline, antilymphocytic IgG and normal horse IgG. Initial counts ranged from 95 to 187/sec. Mean background count 2.5/sec.

antilymphocytic IgG in a dosage which had previously been shown to prolong the survival of skin homografts by a factor of about 2.5 (ref. 8) (1 ml. of 2 g per cent solution daily for 7 days followed by 0.5 ml. daily for 14 days). Six animals received a similar course of normal horse IgG and six others received daily injections of saline. Four days after the last injection of IgG or saline each rat received an intraperitoneal injection of 10 mg normal horse IgG labelled with 10  $\mu$ c. of iodine-131. Sodium iodide (100 mg/l.) was added to the drinking water of all rats commencing 7 days before the injection of labelled protein and continuing to the end of the experiment.

The fate of the labelled protein was investigated in three ways: by counting serial blood samples; by repeated whole body counting; and by counting samples of various tissues removed at autopsy. Blood from a tail vein (0.1 ml.) was diluted with heparinized saline (0.9 ml.) and counted in a well-type scintillation spectrometer incorporating a 2 in. sodium iodide crystal. After tissue samples had been weighed and digested in 6 normal potassium hydroxide, they were counted with the same apparatus. Whole body counting was performed in a ring counter consisting of twelve J26Pb Geiger-Müller tubes shielded with 1.25 in. lead shot which was kindly provided by Dr P. Tothill of the Department of Medical Physics.

The blood and whole body counts are shown in the accompanying graphs (Figs. 1 and 2). It will be seen that rats pretreated with either antilymphocytic or normal horse IgG showed greatly accelerated elimination of the radioactive material from the blood stream (mean biological half-life 0.24 day and 0.38 day, respectively) as compared with the rate of elimination in the control animals pretreated with saline (mean biological half-life 1.55 days). Total body counts showed a similar pattern except that after the initial rapid fall some 2-4 per cent of the original activity remained for up to 5 days. Tissue counts showed that this activity resided principally in the liver and kidneys, where it presumably represents either stages in the breakdown of the injected protein or antigen-antibody complexes.

The results suggest that administration of antilymphocytic IgG in this experimental system does not prevent immunization of the treated animals to horse IgG, thus confirming the hypothesis put forward to account for the failure of initial attempts to achieve immunosuppression with antilymphocytic serum (ALS)<sup>11</sup>. It is now apparent that a high degree of general immunosuppression can be achieved despite immune elimination of the ALS (or IgG) itself, but it is pertinent to ask whether still greater immunosuppression would result if the rate of elimination

Fig. 2. Elimination of normal horse IgG labelled with iodine-131 as determined by whole body counting in rats pretreated with saline, antilymphocytic IgG and normal horse IgG. Initial counts ranged from 1,572–1,930/sec. Mean background count 15/sec.

of the material could be slowed down. This might perhaps be achieved by previous induction of specific immunological tolerance of this material as suggested by Lance and Dresser<sup>12</sup>, by concurrent administration of chemical immunosuppressants, or by reducing the proportion of non-antilymphocytic IgG in the preparation. These possibilities are being investigated.

### Effects of *Corynebacterium parvum* on Immunological Unresponsiveness to Bovine Serum Albumin in the Rabbit

THE immunological response of adult rabbits to bovine serum albumin (BSA) can usually be completely suppressed by an intravenous injection of 10 mg of centrifuged bovine albumin (CBA), but this unresponsive state can in turn be prevented by the injection of a heat-killed suspension of *Corynebacterium parvum* at the same time or 6 days in advance<sup>1</sup>. *C. parvum* also augments the production in the adult rabbit of anti-BSA antibody to either CBA or partially aggregated BSA, and at the same time enhances the relative binding affinity of the antibody<sup>2,3</sup>. We have now been able to show that in neonatal as distinct from adult rabbits *C. parvum* does not impede the induction of immunological unresponsiveness to BSA, and that in adult rabbits a suspension of the organism is ineffective as a means of abrogating a state of unresponsiveness already established.

**Experiment 1.** In the first experiment, eleven newborn New Zealand White rabbits were injected intraperitoneally

with 2 mg (dry weight) of a heat-killed suspension of *C. parvum*<sup>2</sup> less than 12 h after birth and they, together with ten control rabbits, were injected intraperitoneally with 100 mg BSA 6 days later. There was no further treatment until the rabbits were 3 months old, when they all received 50 mg BSA intravenously. They were bled every third day for 30 days, when a second injection of 50 mg BSA was given and the rabbits were bled for another 30 days. Sera were tested for anti-BSA antibody by the Farr technique<sup>4</sup> using 0.20  $\mu$ g N BSA\* and 0.02  $\mu$ g N BSA\* antigen concentrations as previously described<sup>2</sup>.

The ten control rabbits, which received 100 mg BSA 6 days after birth, did not produce detectable anti-BSA antibody after the first injection of BSA, and the same was true after the second challenge for the nine rabbits which survived. Of the eleven rabbits which received *C. parvum* 12 h after birth, only one produced detectable

anti-BSA antibody after the primary challenge with BSA but the amount was not sufficient to permit measurement of the antigen-binding capacity. The same rabbit was the only one to respond to the second challenge, but again too weakly for measurement. In other words, the injection of the *C. parvum* suspension did not interfere with the establishment of immunological unresponsiveness in neonatal rabbits.

**Experiment 2.** Six New Zealand White rabbits were injected intraperitoneally with 100 mg BSA less than 12 h after birth, and 3 months later three of them were injected intravenously with 10 mg (dry weight) of a heat-killed suspension of *C. parvum*. Both groups of three rabbits received 50 mg BSA intravenously 6 days later and were then bled every third day until day thirty of the primary response, when they received intravenous injections of 50 mg BSA and were bled every third day for another 30 days. The primary and secondary sera were tested for anti-BSA antibody as in the first experiment.

The antibody responses of the control rabbits and of those treated with *C. parvum* were identical. Two rabbits from each group did not produce detectable anti-BSA antibody after primary or secondary stimulation with BSA. One rabbit from each group produced low levels of anti-BSA antibody in the primary and secondary responses but the amounts were too low to determine antigen-binding capacities. In other words, *C. parvum* does not abrogate the state of unresponsiveness established by the neonatal injection of 100 mg of BSA.

Our findings on the effects of *C. parvum* on immunological unresponsiveness in adult<sup>1</sup> and neonatal rabbits agree with the results of other experiments. In adult animals, the induction of unresponsiveness can be readily blocked by adjuvant materials such as BCG<sup>5</sup>, *Salmonella typhosa* endotoxin<sup>6</sup>, actinomycin D<sup>7</sup>, zymosan<sup>10</sup>, as well as by *C. parvum*<sup>1</sup>. In neonatal rabbits, on the other hand, it has been shown<sup>5</sup> that large amounts of bacterial endotoxin do not block the induction of neonatally induced unresponsiveness to BSA, and that rabbits 1 day old injected with Freund's adjuvant and 5 days later with 100 mg human serum albumin become unresponsive to the HSA molecule<sup>6</sup>.

These results indicate that either the mechanism of the induction of unresponsiveness is different in the neonatal and adult animal, or that neonatal and adult animals may be affected to different degrees by various adjuvant materials. The observed differences could arise from the relatively massive doses of antigen, with respect to body weight, administered to neonatal animals in order to induce a profound degree of unresponsiveness; only relatively small quantities of aggregate-free antigen are

needed to induce a profound degree of unresponsiveness in the adult rabbit<sup>1</sup>. Certainly Paraf *et al.*<sup>6</sup> report that complete Freund's adjuvant does block the induction of unresponsiveness in the neonatal rabbit to 1 mg HSA. Smith<sup>5</sup>, however, indicates that bacterial endotoxin does not block the induction of unresponsiveness to various doses of BSA in the neonatal rabbit. Whether unresponsiveness to high and low doses induced in the neonatal and adult animals arises by different mechanisms or simply results in varying durations or degrees of unresponsiveness remains to be determined. The mechanism of adjuvant action of many substances is still unknown, although with the accumulation of recent data about the induction of unresponsiveness, it would appear that adjuvant materials augment the production of antibodies simply by blocking the induction of unresponsiveness.

The question which now arises is why materials such as *C. parvum*, which act as powerful adjuvants in adult animals, apparently possess no adjuvant activity in neonatal animals. Elucidation of these differences may throw light on the maturation processes of the lymphoid tissues and on the role of different cellular elements in the initiation of the immune response.

## Histidine Decarboxylase Inhibitors and the Survival of Skin Homografts

CHANG and I (unpublished results) have observed that skin homografting in rats results in a significant increase in urine histamine excretion and that the greatest histamine excretion occurs within a 3 day period of the observed time of graft rejection. The possibility that intracellular histamine metabolism and histamine formation from histidine decarboxylase activity might be involved in the mechanics of homograft rejection led to the present study of the effect of histidine decarboxylase inhibitors on rat skin homograft survival.

Three histidine decarboxylase inhibitors were used—the alpha hydrazino analogue of histidine, semicarbazide and NSD-1055 (4 bromo-3-hydroxy benzyloxyamine). The effectiveness of the alpha hydrazino analogue of histidine and NSD-1055 as potent inhibitors of histidine decarboxylase has been described<sup>1</sup>, while the combination of semicarbazide administration and a pyridoxine deficient diet has been reported<sup>2</sup> to reduce histidine decarboxylase activity to 10–20 per cent of normal.

The histidine analogue (aHH) and NSD-1055 were injected intraperitoneally and the semicarbazide was given

subcutaneously. Control injections of physiologic saline solution were given intraperitoneally twice daily. Injections were started on the day before grafting and each was 1 ml. They were continued daily thereafter.

Skin homografts of standard size were carried out between the inbred P.A. and Lewis rat strains. Circular grafts of abdominal skin 3.5 centimetres in diameter were cut from a pattern and were secured to an area of equal size on the back of the recipient by means of small Michel clips. All of the recipients were females and weighed approximately 200 mg. The grafts were not covered by dressings and the animals were kept in individual cages. The grafts were inspected daily and the percentage of rejection was recorded. Any portion of the graft which was hard and obviously devitalized was regarded as rejected. The use of a comparatively large graft of standard size on animals of uniform size permitted calculation on a daily basis of the percentage of total grafted area rejected in any group of animals as a pooled rejection response. In the calculation of mean survival time of grafts, any graft with 50 per cent or more rejection was regarded as rejected.

Table 1. SUMMARY OF SKIN HOMOGRAFT SURVIVAL TIMES

No. of rats	Treatment*	Total daily dose (mg/kg)	Mean survival time (days)	Range of survival (days)	Change against controls (per cent)	Mortality of rats before completed rejection
P.A. to Lewis						
20	Control		6.4	5–8		1/20
20	aHH	200	13.0	6–29	+103†	2/20
Lewis to P.A.						
20	Control		8.1	6–14		0/20
20	aHH	200	20.9	13–33	+170†	6/20
10	PDD		10.1	7–14	+25‡	0/10

† 0.01 significance level by Wilcoxon rank sum test.

‡ 0.05 significance level by Wilcoxon rank sum test.

Twenty control Lewis rats were grafted with P.A. skin (Table 1). The median survival times of these control grafts was 6.4 days. When 20 P.A. to Lewis grafted animals were given 100 mg/kg of aHH twice daily, the median survival time was increased significantly to 13.0 days.

Twenty control Lewis to P.A. homografts had a median survival time of 8.1 days. Administration of aHH (100 mg/kg twice daily) prolonged the median survival time of grafts to 20.9 days. The inhibition of graft rejection was even more impressive when the cumulative total area of rejected graft in thirty aHH treated rats was compared on a daily basis with the area of rejection in twenty control rats (Fig. 1).

The greatest time of survival for grafts in Lewis to P.A. grafted animals was obtained by giving semicarbazide (SC) to pyridoxine deficient diet rats. The animals received semicarbazide (50 mg/kg) twice daily. The pyridoxine deficient diet (PDD) was started 10 days before grafting. The median survival time of animals on PDD only was 10.1 days. When SC was given in addition to the PDD, the median survival time was increased to 35.5 days. The cumulative total area in which grafts were rejected was less than that of control rats and rats given PDD only (Fig. 1). NSD-1055 was less effective in increasing the survival of Lewis to P.A. skin homografts. The median survival time for 100 mg/kg once daily was 13.0 days and that for 75 mg/kg twice daily was 13.5 days. Work in progress suggests that the dosage level of SC is more critical than the duration of PDD prior to grafting and that PDD also enhances the rejection inhibiting action of aHH.

This investigation does not establish the biological mechanism by which these histidine decarboxylase inhibitors prolong survival of skin homografts. The

Fig. 1. Graph showing daily percentage of total grafted area rejected in control animals (C) as compared with animals on PDD, aHH and PDD+SC.

action may be an anti-inflammatory one caused by interference with intracellular histamine formation or it may be related to diminished antibody formation. This would be secondary to an enhanced pyridoxine deficiency produced by a pyridoxal trapping action of the histidine decarboxylase inhibitors. Pyridoxal phosphate is the co-enzyme of histidine decarboxylase and Stoerk and Eisen<sup>3</sup> have demonstrated an inhibition of circulating antibody production in pyridoxine deficiency, a suppression not encountered in paired weighed inanition controls and full controls.

## BIOLOGY

### Gibberellins in the Red Alga *Hypnea musciformis* (Wulf.) Lamour.

GIBBERELLINS, or substances like gibberellin, have been detected in vascular plants belonging to diverse taxonomic groups<sup>1</sup>, and there is evidence for their occurrence in a species of green alga<sup>2</sup> and two species of brown algae<sup>2,3</sup>. We report here the presence of gibberellin-like activity in an extract from a species belonging to a further principal group of the plant kingdom, the red algae.

The extraction method used was essentially one of those previously described for the extraction of acidic gibberellins from higher plants<sup>4</sup>. Plants of *Hypnea musciformis* (Wulf.) Lamour. were collected from coastal reefs near Perth, and deep frozen until required. The thawed material (mass 1 kg) was homogenized in 60 per cent aqueous acetone and allowed to stand in the cold for 24 h before filtration. The acetone was distilled off *in vacuo*, and the aqueous residue adjusted to pH 2.5 and extracted three times with ethyl acetate. The total ethyl acetate extract was reduced in volume and extracted three times with phosphate buffer at pH 6.2; the buffer phase was in turn adjusted to pH 2.5 and extracted three times with ethyl acetate. The ethyl acetate extract was reduced in volume and chromatographed on Whatman No. 3 paper,

using *n*-butanol : 1.5 normal  $\text{NH}_4\text{OH}$  3 : 1 (upper phase) as a descending solvent. After drying, the chromatogram was divided transversely into ten equal strips, and each strip was eluted with acetone/water. Each eluate was dried and taken up in 0.5 ml. of 50 per cent ethanol for assay using dwarf maize of the varieties  $D_1$  and  $D_5$  (ref. 5). Each maize seedling was treated with 0.05 ml. of the eluate, and measured 8 days after treatment. The assay was carried out under fluorescent lights at 25° C. Results are presented in Fig. 1.

It is clear that biological activity was present in the extract, centred in two broad zones at  $R_F$  0.2–0.4 and 0.5–0.8. Comparison of these  $R_F$  and bioassay data with those of gibberellins  $A_1$ – $A_9$  (ref. 6) indicates that activity at 0.2–0.4 could have been caused by any of the gibberellins  $A_2$ ,  $A_3$  and  $A_6$ , while the activity at 0.5–0.6 could be attributed to  $A_7$ . It may be tentatively suggested that the activity observed at  $R_F$  0.0–0.1 and 0.7–0.8, detected in the  $D_1$  but not the  $D_5$  assay, could not have been caused by any of the gibberellins  $A_1$ – $A_9$ . Only  $A_1$  has been found to be more active in the  $D_1$  than the  $D_5$  assay<sup>7</sup>, but this compound has an  $R_F$  in the region of 0.3 in the solvent system used here<sup>8</sup>. It is not possible to estimate the total level of gibberellin activity in the extract, as dose-response curves are not available for comparison with known  $GA_3$ . The general levels of activity are, however, probably of the same order as those found in extracts of shoots of higher plants<sup>1</sup>.

It has been reported that  $GA_3$  stimulates the growth of two species of the genus *Porphyra*<sup>8,9</sup>. These observations, together with the results reported here, suggest very strongly that gibberellins are involved in growth regulation in the red algae.

Fig. 1. Percentage elongation of maize seedlings treated with eluates from a chromatogram of a *Hypnea* extract. A, Results using maize variety  $D_5$ ; B, results using maize variety  $D_1$ . Stippled areas represent growth significantly different from the controls at less than the 5 per cent level (t test).

### Effect of Light on Cell Division in Plant Tissue Cultures

LIGHT strongly influences many aspects of growth in plants. There have, however, been few studies on the effects of light on cell division in non-green plant tissue cultures. In the course of investigating the physiology of cell division in developing callus cultures of *Helianthus tuberosus* it has been observed that light can have an inhibitory effect on cell division.

Observations<sup>1-3</sup> have shown the course of change in cell number with time in explants taken from tubers of the Jerusalem artichoke and cultured in contact with a medium containing 20 per cent coconut milk and  $10^{-6}$  molar, 2,4-dichlorophenoxyacetic acid. It has also been

Fig. 1. Percentage increase in cell number per explant with time of incubation. Explants were removed from tubers in green light and cultured in groups of 80 in 12 ml. medium containing  $10^{-6}$  molar 2,4-D, in 9 cm Petri dishes, at 25° C. Agitation was on a reciprocating shaker operating at 50 c/s with a 7 cm displacement. The explants were grown in total darkness (▲), 120 ft.-candles (●) and 450 ft.-candles (■). Both light sources were mixed fluorescent and tungsten. Cell number data were derived from counts on 5 per cent chromic acid macerates of five explant samples.

Fig. 2. Percentage increase in cell number per explant with time of incubation. Explants were prepared and cultured as described in Fig. 1. For the first 30 min after excision, the explants were exposed to total darkness (▲), 18 ft.-candles fluorescent light (○) and 120 ft.-candles (●) and 450 ft.-candles (■), mixed fluorescent and tungsten light. Subsequent culture was in total darkness. The vertical line represents the S.E. of the difference between the dark and light treatments.

shown<sup>2,3</sup> that the first few divisions are synchronous. These observations were made with an experimental procedure which involved exposure of the tubers and of the excised explants for periods of 30–90 min to about 18 ft.-candles from a fluorescent source, and exposure to the light from a tungsten lamp when the cultures were being inspected. Subsequently it has been found that the proportion of cells in the explant that divide at the first synchronous division increases from 45 to 90 per cent when the explant is removed in low intensity green light and then cultured in total darkness on a medium without coconut milk but in the presence of 2:4-dichlorophenoxyacetic acid (2,4-D) at  $10^{-6}$  moles/l.

Results of two experiments designed to show the light effect in division are given in Figs. 1 and 2. The explants were obtained with techniques described elsewhere<sup>1</sup>, and grown in bulk culture in a liquid medium.

In the first experiment (Fig. 1), the explants removed in low intensity green light were exposed throughout the period of culture to two intensities of light, and their growth compared with a control in total darkness. In the second experiment (Fig. 2), the explants were exposed to various light intensities for a period of 30 min after excision. They were then cultured in total darkness.

It is clear from the results presented in Fig. 1 that the number of cells formed at the first division is significantly greater in the dark than in the light. Continuous light therefore has a strongly depressing effect on cell division.

Preliminary exposure for a short period after excision has a sharply depressing effect on division at all light intensities (Fig. 2). The explants excised in green light and cultured in total darkness form considerably more cells at the first synchronous division than do those exposed to light for the first 30 min after excision. Clearly radiation other than dim green light has a strongly depressive effect on division in this system and most of the effect is exerted in the period immediately after excision. It may be noted that the synchronous pattern is displayed in all conditions in this experimental series.

We thank Professor R. Brown and Dr J. E. Dale for their advice, and the Sir David Baxter Scholarship Fund for a studentship to one of us (R. S. S. F.).

# Rapid Bioassay for Phytokinins based on Transpiration of Excised Oat Leaves

SEVERAL compounds which exhibit phytokinin activity have been reported<sup>1-7</sup>. Current interest in the isolation of this group of compounds indicates that a rapid technique for the detection of low concentrations of phytokinins would be useful. This communication describes such a technique and reports various aspects of transpiration stimulated by phytokinin.

The technique is based on transpiration of excised leaves of a species of *Avena* (oat) induced by phytokinin. This phenomenon is not related to increased uptake of water induced by growth substances<sup>8,9</sup>, nor is it related to cell enlargement of leaf disks<sup>9</sup>. Induced transpiration of excised oat leaves, however, is similar to stimulated transpiration of excised barley leaves<sup>10</sup>.

Initially distinct differences in sensitivity of excised leaves to stimulated transpiration were observed among various genera of the grass family. Species of *Avena*, *Triticum* and *Hordeum* proved to be the most sensitive. These genera were compared to determine the most sensitive species. Results (Table 1) showed that *Avena* species were more sensitive to transpiration induced by phytokinin than species of *Triticum* or *Hordeum*, and species of *Triticum* were more sensitive than species of *Hordeum*. When the quantity of water transpired was expressed in mg/cm<sup>2</sup> of leaf surface, the rates of transpiration of species of *Avena* were about four times that of untreated leaves.

Table 1. COMPARISON BETWEEN TRANSPIRATION RATES OF EXCISED *Avena*, *Triticum* AND *Hordeum* LEAVES, TREATED WITH 2 µg/ml. OF KINETIN

	Transpiration expressed (mg/cm <sup>2</sup> ) of leaf surface*		
	Treated	Untreated	Percentage increase
Oats	292	73	400
Wheat	184	50	361
Barley	117	83	141

\* These calculations involved two surfaces for each leaf.

Because species of *Avena* proved to be the most sensitive to transpiration stimulated by phytokinin, plants of the cultivar 'Fulgrain' (C.I. 4389) were propagated in a growth chamber in the following conditions. Approximately six plants were grown in 8 in. clay pots containing a 2:1 soil-peat mixture. The growth chamber was maintained at 20°-22° C. Plants were subjected daily to a fluorescent-incandescent system of light of about 1,000 ft.-candles for 15 h.

When plants were about 28 days old (the stage of the fourth leaf), the third leaf of each was excised. Later the fourth, fifth and sixth leaves were used. In a given test, however, leaves were taken from the same position on the plant because differences in leaf size and physiological condition influenced the rate of transpiration. Excised leaves were trimmed to either 30 or 38 cm with a sharp scalpel, and basal ends were immersed in various concentrations of the compound to be assayed. In most experiments, two 30 cm leaves were used in each replication; however, one 38 cm leaf gave comparable results. When it was desirable to know precisely the quantity of test material absorbed, excised oat leaves were treated in 15 ml. calibrated centrifuge tubes; the amount taken up could therefore be calculated. Leaves thus treated were maintained in the solutions to be assayed for 24 h at 20°-22° C under continuous fluorescent light (about 400 ft.-candles). Temperature was maintained with an air conditioner; the relative humidity therefore fluctuated between 50 and 80 per cent. Treated leaves were then transferred to calibrated centrifuge tubes containing distilled water and placed under continuous fluorescent light (400 ft.-candles). The amount of distilled water lost from

the tubes after 24 h was recorded. The difference in amount of water lost between treated and untreated leaves was a measure of the quantity of phytokinin in the test solution. The lack of change in leaf weights, after treatment with kinetin, as well as porosity data and visual observations (supplied by Dr J. E. Pallas, jun.), indicated that the water taken up was transpired. Transpiration induced by phytokinin also occurred in the absence of light; however, the rate of transpiration under 400 ft.-candles was about twice as great as that in the dark. Although the optimum assay time is 48 h, the time can be reduced to about 24 h (12 h treatment, 12 h in distilled water). When high sensitivity and quantitative results are desirable the 48 h period is recommended.

Ranges of sensitivity for two cytokinins are shown in Fig. 1. The lower limit of this test was about 0.001 µg/ml. for zeatin (supplied by Dr C. O. Miller) and 0.005 µg/ml. for kinetin. Thus the transpiration test is about ten times more sensitive than the chlorophyll retention<sup>6</sup> and the barley root inhibition tests<sup>11</sup>, but it is less sensitive than the carrot phloem test<sup>12</sup>. It is interesting to note that the order of sensitivity of the carrot phloem method is similar to the oat transpiration test—both are more sensitive to zeatin than to kinetin. Ranges of sensitivity (Fig. 1) for zeatin and kinetin are somewhat different. The effective range for zeatin is about 0.001-0.1 µg/ml. and it is 0.005-1 µg/ml. for kinetin. This difference is not surprising because the toxicity threshold for excised oat leaves is about 5 µg/ml. for kinetin and 0.5 µg/ml. for zeatin.

Fig. 1. Effects of concentration of phytokinin on the rate of transpiration of excised oat leaves. ●, Zeatin; ▲, kinetin.

Gibberellic acid stimulates transpiration of excised primary barley leaves<sup>10</sup>. When gibberellic acid was used in the oat leaf transpiration test ( $1.5 \times 10^{-4}$  molar) it did not cause a measurable increase in transpiration. Excised oat leaves therefore exhibit a greater degree of specificity for phytokinins than excised barley leaves.

The advantages of the assay described here can be summarized as follows: (a) short assay time (24-48 h); (b) high sensitivity (zeatin 0.001 µg/ml., kinetin 0.005 µg/ml.); (c) quantitative (see Fig. 1 for approximate linearity ranges); (d) permits accurate measure of amount

absorbed; (e) insensitive to compounds other than phytochemicals.

### Absence of Nodule Formation on *Ceanothus cuneatus* in Serpentine Soils

YOUNGBERG has reported that *Ceanothus cuneatus* Nutt., a woody shrub native to semi-arid regions of California and Oregon, has clusters of nitrogen-fixing nodules on its roots<sup>1</sup>. During the past 2 years, I have examined the root systems of this species in seven populations in Oregon and California with particular attention to the parent material of the soils involved (Table 1). No plant less than 3 dm tall was examined.

Table 1. POPULATION NODULATION DATA GROUPED BY PREDOMINANT PARENT MATERIAL

Locality and parent material	No. of plants	No. nodulated
3-2 km S. of New Idria, Calif.; serpentine	21	0
Store Gulch, 16 km W. of Selma, Ore.; serpentine	18	1
6-6 km W. of Selma; serpentine	15	0
Star Flat (A), 6-4 km W. of Selma; serpentine alluvium	20	1
Totals	74	2
Mean nodulation = 0.03		
Star Flat (B), 20 m W. of (A); mixed alluvium*	14	11
Rough and Ready Creek Wayside, Ore.; mixed alluvium*	4	3
6-4 km E. of Copper, Ore.; greenschist	11	2
Totals	29	16
Mean nodulation = 0.55†		

\* Alluvium composed of serpentine and other parent materials.

† Differs from the mean of serpentine populations at the 1 per cent level of significance using a *t*-test, and at the 0.5 per cent level of significance by the  $\chi^2$  method. The standard error of the difference between the means is 0.095.

The percentage of plants nodulated on non-serpentine soils ranged from 18 per cent to 79 per cent in separate populations, while the percentage of plants nodulated on serpentine soils ranged from 0 per cent to 6 per cent. The mean percentage of nodulated plants in populations growing on non-serpentine soils is lower than expected. This is a reflexion of both the choice of populations and the low number of plants examined, and would probably be higher in other populations growing in more suitable habitats. The mean is also lowered by sampling populations on soils derived from greenschist, a rock containing minerals which are also found in serpentine rock, and populations on alluvial soils contaminated by serpentine material.

I think that the paucity of nodulated plants growing on serpentine soils results from one or more of three factors:

(1) low concentrations of major (NPK) nutrients; (2) low available molybdenum; (3) toxic concentrations of chromium, nickel, and other heavy metals<sup>2</sup>. Low available molybdenum may be of particular significance because plants which fix nitrogen require more molybdenum than those which do not<sup>3</sup>. Exclusion of free-living<sup>4</sup> and symbiotic nitrogen-fixing organisms from serpentine soils may partly explain the low concentrations of nitrogen in serpentine soils. The few plants that were found nodulated on serpentine soils grew only in microsites where other rock types and soils had been added by colluvial or alluvial mixing. This apparently has had an ameliorating influence on the effects of the predominantly serpentine soil.

I thank J. C. Hickman, and Drs S. A. Cook and P. W. Frank for their advice.

### Spicules in the Skeleton of *Tremacystia d'orbignyi* (Hinde)

THE Sphinctozoa<sup>1</sup> or Thalamida<sup>2</sup> are extinct marine organisms with a chambered calcareous skeleton, which are widely regarded as sponges because spicules like those of existing Calcarea have been figured from Cretaceous species. The best authenticated spicules have been those of *Tremacystia* [*Verticillites*] *d'orbignyi* (Hinde), which were stated by Hinde<sup>3</sup> to be figured from examples detached and mounted separately.

In a paper introducing the treatment of this group in the *Osnovy Paleontologii*<sup>4</sup> Zhuravleva and Rezvoi<sup>5</sup> have claimed that these spicules are imaginary. They maintain that the sphinctozoan skeleton has only a concentrically fibrous structure around radial canals which run through it. When the fibrous sheaths around closely spaced canals are in contact, a tri-radiate space may be left between a group of three canals, and Hinde<sup>3</sup> is believed to have mistaken such spaces for spicules. No authors since Rauff<sup>6</sup> have recorded any spicules, and photographs only show their absence. On these grounds the authors conclude that their skeleton has nothing in common with that of calcareous sponges, and revive the suggestion<sup>7</sup> that they may be related to the Archaeocyatha. In the *Osnovy Paleontologii*<sup>4</sup> volume, which treats sponges and archaeocyathids, it is stated that the skeleton of Sphinctozoa has not even a distant resemblance to those of any existing sponges, and the group is made a class *incertae sedis* between the Porifera and Archaeocyatha.

Spicules of *T. d'orbignyi*, as seen in two of Hinde's original slide preparations (British Museum (Natural History), Nos. S.1425, S.1426) are shown in Fig. 1. His slides contain examples of all the types of spicules which he figured<sup>3</sup>, mounted in balsam as he stated. Spicules are also seen on the surfaces of all his original specimens (Nos. S.8785-8787 and S.8791-8800), as well as in others examined. As he stated<sup>3</sup>, the large forms and their smaller variants (Fig. 1, except bottom right) are sagittal quadriradiates or tri-radiates, like those of existing Calcarea. The finely "fibrous" structure in which these spicules are embedded is also composed of separable spicules (Fig. 1, bottom left and right).

The notion that Hinde mistook spaces in a purely fibrous structure for spicules is thus clearly mistaken. It

Fig. 1. Spicules of *Tremacystia d'orbignyi* (Hinde), from Hinde's slide preparations S.1425, S.1426 ( $\times 110$ ).

had also little justification, because Hinde could not have mounted detached spicules, as he stated<sup>3</sup>, had they not existed.

I thank the Trustees of the British Museum (Natural History) and Dr H. Ball for permission to study Hinde's material, and Mr S. Ware for locating it.

### Diurnal Variation of Adrenocortical Function in Hypophysectomized Rats with Multiple Heterotopic Pituitary Homografts

WE have shown that hypophysectomized male rats bearing ten heterotopic, homografted pituitaries under the renal capsules have nearly normal adrenal weight and considerable, though subnormal, adrenal corticosterone production<sup>1</sup>. Because adrenal weight and production of corticosterone was markedly reduced in hypophysectomized rats without pituitary homografts, we concluded that the heterotopic pituitary has adrenal-maintaining activity presumably by means of the secretion of ACTH. Furthermore, because many investigators have shown that a single heterotopic pituitary exhibits only very slight adrenal-maintaining activity<sup>2-4</sup>, we concluded that multiple heterotopic pituitaries maintain adrenal weight by virtue of their collective secretion of individually small amounts of ACTH. The present communication deals with studies of diurnal variation in the function of the cortex of the adrenal glands in rats with pituitary homografts and provides evidence that direct connexion between the brain and pituitary is not essential for the rhythmic activity of the pituitary-adrenocortical axis.

Recipient male rats of the Sprague-Dawley strain, with a history of a relatively high degree of inbreeding in a small, closed colony, weighed approximately 120 g at the time of pituitary grafting. Ten whole pituitaries from 14 day old donor rats of the same strain, but of unselected sex, were transplanted under both renal capsules. The animals were housed in a room of constant temperature with 12 h of light, 12 h of dark cycles beginning at 6 a.m., and were fed water and 'Purina' laboratory chow *ad lib*. Four weeks after transplantation, the animals were hypophysectomized by the parapharyngeal approach. Two weeks later, diurnal variation of adrenocortical function was studied. Blood from the trunk was collected in heparinized beakers after decapitation at 8.30 a.m. and 4.30 p.m. Blood specimens were promptly centrifuged and the plasma analysed for corticosterone by the method of Mattingly<sup>5</sup>, and adrenal glands were weighed on a torsion balance and analysed for corticosterone.

The mean ( $\pm$  standard error) relative adrenal weight of the hypophysectomized, grafted animals was slightly greater than that of the unoperated controls ( $15.7 \pm 0.5$  mg/100 g body weight as against  $13.5 \pm 0.3$  mg/100 g body weight) but the difference was not statistically significant. Furthermore, the adrenal weights of the animals of both groups killed in the morning were not statistically different from the adrenal weights of the respective group killed in the afternoon. The adrenal glands of the animals with pituitary grafts were, however, much larger than those of six hypophysectomized controls ( $6.0 \pm 0.2$  mg/100 g body weight). The adrenal function data are summarized in Table 1. The afternoon concentration of plasma corticosterone was higher than that found in the morning both in the hypophysectomized animals with grafts and in the unoperated controls. Similarly, the adrenal corticosterone content was greater in the afternoon than in the morning in both groups. These data indicate that diurnal variation of adrenocortical function may occur despite the absence of direct connexion between the brain and the adenohypophysis. The data do not, however, shed light on the question of the location of the biological clock regulating pituitary-adrenal rhythmicity.

A location of the biological clock in the brain is supported by several observations including those of Slusher<sup>6</sup>, who found that hypothalamic lesions may interfere with diurnal variation of plasma corticosterone, although they do not alter the response of corticosterone to stress. The finding of Galicich *et al.*<sup>7</sup> who showed in mice that cerebral ablation above the pons, but not above the thalamus, interfered with circadian variation in the content of pituitary ACTH, provides additional evidence that the suprapontine brain participates in the regulation of diurnal variation in pituitary-adrenocortical activity. Finally, the observation that anticholinergic agents block the circadian pattern of plasma 17-hydroxycorticoids in cats<sup>8</sup> supports the hypothesis that the central nervous system is involved in the circadian cycle.

The physiological control of heterotopic pituitary secretion of ACTH also has not been fully explained. One possible mechanism for this control is by secretion of a neurohumour (CRF) from the hypothalamus which is transported through the general circulation to reach the heterotopic pituitary and stimulate secretion of ACTH. Our previous finding that exogenous corticoids depress heterotopic ACTH secretion in hypophysectomized rats with multiple heterotopic pituitary homografts<sup>1</sup> lends tentative support to the hypothesis that the heterotopic pituitary remains under the control of the hypothalamus,

Table 1. DIURNAL VARIATION OF ADRENOCORTICAL FUNCTION

Group	Plasma corticosterone $\mu$ g/100 ml.		P <sup>†</sup>	Adrenal corticosterone $\mu$ g/pair glands		P
	a.m.	p.m.		a.m.	p.m.	
Homografted and hypophysectomized	$5.2 \pm 1.0^*$ (14) <sup>†</sup>	$9.7 \pm 0.8$ (14)	< 0.001	$0.15 \pm 0.03$	$0.27 \pm 0.04$	< 0.01
Unoperated controls	$5.6 \pm 0.6$ (12)	$16.6 \pm 2.5$ (13)	< 0.001	$0.13 \pm 0.01$	$0.26 \pm 0.08$	< 0.02

\* Mean  $\pm$  standard error.

<sup>†</sup> Number of animals per group.

<sup>‡</sup> Probability that the difference between the morning/afternoon mean was due to chance.

because the bulk of current evidence supports the view that corticosteroids suppress secretion of ACTH after a primary action in the median eminence of the hypothalamus<sup>9</sup>. Removal of the entire forebrain, but not cerebral decortication, was also found to diminish adrenocortical function in hypophysectomized rats with pituitary homografts<sup>10</sup>, which suggests that the heterotopic pituitary depends on stimulation by the subcortical forebrain, perhaps by means of a systemically transported neurohumour of hypothalamic origin. Though still speculative, it is attractive to explain our present finding of diurnal rhythm of adrenocortical function in rats with heterotopic pituitaries by postulating that the brain rhythmically secretes a neurohumour which is transported through the general circulation to stimulate the heterotopic pituitary and, in turn, the adrenal cortex.

### Heritable Resistance to Warfarin in Rats

WARFARIN and other anticoagulants are used for the destruction of rats throughout the world and have been by far the most successful materials ever introduced for this purpose. Since 1960, however, apparently independent outbreaks of resistance to warfarin in *Rattus norvegicus* have been reported from Scotland<sup>1</sup>, Denmark<sup>2</sup> and Wales<sup>3</sup>.

Starting with wild rats caught in Wales, rats resistant to warfarin have been crossed with domesticated albino rats of unknown origin in this laboratory for five successive generations. The offspring in each generation were fed *ad lib.* for six days on medium oatmeal containing 0.005 per cent warfarin, a procedure which is lethal to about 93.4 per cent of rats from our laboratory stock. Table 1 shows that mortality has not differed significantly from the figure of 46.7 per cent expected on the hypothesis that resistance to warfarin depends on a single dominant autosomal gene. A similar result, relating to rats of Scottish origin resistant to warfarin, has been mentioned by Drummond and Bentley<sup>4</sup>, who refer to unpublished work by P. M. Sheppard and D. A. Price Evans of the University of Liverpool.

Twenty-two experimentally naive fifth generation rats, half of which would be expected to possess the inferred gene for resistance to warfarin were subcutaneously injected with 1 mg/kg of warfarin dissolved in dimethyl formamide. Blood samples were taken retro-orbitally under ether or 1:1 oxygen:carbon dioxide anaesthesia immediately before and 24 h after injection, and the one-stage prothrombin times measured using Diagen 'Two-Seven-Ten' reagent. Two weeks after injection the rats were given the six day feeding test. It can be seen from Table 2 that except for rat No. 22 the animals fell into two distinct groups: in one the injected warfarin had little or no effect on the prothrombin time and the animals

\* The blood sampling procedure was unsuccessful with these rats before the feeding test; the times given are for blood samples taken before and after a further 1 mg/kg injection given three weeks after the end of the feeding test.

survived the feeding test; in the other there was a large response to the injection and the rats died as a result of the feeding test. Rat No. 22 resembled the susceptible animals and differed from the resistant ones in showing typical signs of warfarin poisoning (congested lungs and bleeding from the nose) and reducing its food consumption during the last three days of the feeding test.

The finding that resistant animals are resistant to both ingested and injected warfarin shows that the resistance can not wholly be accounted for by failure to absorb the anticoagulant from the gut. Further, the difference between the prothrombin times of resistant and susceptible animals injected with warfarin shows that the resistance is related to the level of the blood clotting factors. The underlying mechanisms of resistance may, however, involve reduced capillary fragility, slower turnover of the clotting factors, more rapid detoxication or excretion of warfarin, increased binding of the anticoagulant to plasma proteins, increased storage of vitamin K—which is antidotal to warfarin—or, as in man<sup>4</sup>, more efficient utilization of vitamin K. It is hoped that further research will show in which, if any, of these mechanisms the resistance resides.

The difference between resistant and susceptible rats injected with warfarin, in terms of the activity of clotting factors of the prothrombin complex, also provides a means of distinguishing the two types of rat quickly and reliably,

which should facilitate investigations of resistance to warfarin in the field.

### Indication of Cyclic Reproductive Activity in Abyssal Organisms

THE difficulty in sampling the sea floor at depths greater than 2,000 m (ref. 1), where the abyssal zone is believed to start<sup>2</sup>, is so great that even today there are not many samples. The yield in specimens from the samples which have been taken is low for any given species of animal and it is seldom that one species has been repeatedly taken. These factors have combined to permit few observations on the biology of any one species. In general, so few ovigerous or gravid specimens of deep sea isopods have been taken that Wolff<sup>3</sup> has reasoned that gravid specimens hide in the mud, thus avoiding capture, or that the breeding period is short and occurs once every second or third year. An example of the absence of gravid female specimens can be found in the report by Menzies<sup>4</sup> on 123 abyssal species of marine isopods representing 447 specimens. In six cases gravid specimens were reported.

Fig. 2. Ovigerous female of *Storthingura birsteini* Menzies, 1962 (ref. 4). (Length 18 mm, maximum width 8 mm) from Scotia Sea, depth, 3,731–3,804 m.

endogenous solar and lunar rhythmicity persists in organisms when they are subjected to constant conditions in the laboratory<sup>5</sup>. We consider it reasonable to suppose that deep sea organisms might show persistent reproductive cycles in the absence of seasonal environmental changes which might reflect their origin from shallow water organisms. The data which we present for species of the genus *Storthingura* support this view (Fig. 1,

Percentage of gravidity represents the percentage of ovigerous females in the total number of males and females in a population sample.  
\* Manuscript names used by the authors.

There are no known seasonal environmental changes in the deep sea comparable with the magnitude of seasonal change at the sea surface. It might be reasonable to suppose therefore that unusual breeding conditions exist. It has, however, been convincingly demonstrated that

Fig. 1. Breeding activity in sub-Antarctic abyssal species of *Storthingura* (Crustacea, Isopoda). ●, *S. birsteini*; ○, *S. scotiae*\*; ○, *S. robustissima*; ○, *S. eltaniae*\* and *sepioides*\*; ○, *S. triptisipinosa*. (Species with an asterisk are manuscript names used by the authors.)

Table 1). A gravid female is shown in Fig. 2. Quite obviously the data are necessarily scanty. They deny neither of Wolff's<sup>3</sup> speculations, but instead suggest another mechanism—seasonal breeding cycles—comparable with those known for shallow water animals.

## BIOCHEMISTRY

## Inhibition of Gastric Acid Secretion by Bacterial Lipopolysaccharide

Baume, Nicholls and Baxter report the potent effect of lipopolysaccharide on gastric secretion as if this were a new observation<sup>1</sup>. But the effect was clearly described in 1950 (ref. 2). We have made similar experiments in conscious dogs with vagally denervated pouches of the body of the stomach. Gastric secretion was stimulated by a low dose of histamine given by constant intravenous infusion (100 µg/h of histamine base). Gastric acid secretion was abolished by doses of 10 µg/kg of *Pseudomonas* polysaccharide pyrogen ('Piromen', Flint Laboratories Inc.) given intravenously over a period of about 20 min during stimulation with histamine. Secretion failed progressively over 2-3 h during which time the dogs developed pyrexia as indicated by a thermistor in the rectum (Fig. 1). In control experiments in which saline was given in place of 'Piromen' secretion was maintained.

When gastric acid secretion is stimulated in conscious dogs by feeding, by intravenous 2-deoxy-D-glucose, or by gastrin infusion, atropine sulphate (0.1 mg/kg intravenously) practically abolishes the secretion. Under similar conditions secretion stimulated by histamine is virtually unaffected<sup>3</sup>. Also, secretion stimulated by histamine is much more resistant to depression caused by elevation of the plasma calcium concentration than is secretion stimulated by gastrin<sup>4</sup>. From this we deduce that histamine acts, as is generally supposed, directly on the secreting cells. The potent action of lipopolysaccharide against secretion stimulated by histamine is therefore likely to reflect an effect on the secretory mechanism and not on intrinsic or extrinsic nerves. We agree with Baume *et al.*<sup>1</sup> that alterations in gastric blood flow could be responsible for the effect.

The slow development of inhibition of secretion in our experiments—it seemed to run parallel with rise in body temperature—suggests that inhibition of secretion, like pyrexia, depends on development of a mediator such as leucocyte bacterial pyrogen<sup>5</sup>. It should, however, be mentioned that it has been claimed that in rats lipopoly-

saccharide has gastric secretory inhibitory activity unrelated to its pyrexia effect<sup>6</sup>.

The significance of these observations is two-fold: first, the potency of bacterial lipopolysaccharide in inhibiting gastric secretion merits further investigation; and second, gastric secretory inhibition by biological extracts and other substances should always be accompanied by temperature recordings over several hours.

A., and Kundrats, S., *Gastroenterology*, **47**, 171 (1964).Distribution of the Adrenaline-forming Enzyme in the Adrenal Gland of a Snake, *Xenodon merremii*

CHROMAFFIN cells are present in two separate loci in the adrenal gland of the snake, *Xenodon merremii*. Most are distributed within a homogeneous ribbon on the periphery of the gland; these cells contain<sup>1</sup> and produce<sup>2</sup> large amounts of noradrenaline but little adrenaline. The remainder of the chromaffin cells are scattered among the adrenal cortical cells in the central portion of the gland. These cells contain large amounts of the methylated amine, adrenaline<sup>1</sup>.

The conversion of noradrenaline to adrenaline is catalysed by an enzyme, phenylethanolamine-N-methyl transferase (PNMT)<sup>3</sup>. In mammals almost all of this enzyme is found in the adrenal medulla, where its activity<sup>4</sup> and synthesis<sup>5</sup> are stimulated by the adrenocortical steroids which perfuse this organ in high concentrations. The observation that, in *Xenodon*, there is a high concentration of adrenaline in the central chromaffin cells suggested that PNMT in this species might also be controlled by cortical hormones, so we examined the regional distribution of this enzyme in the adrenals of *Xenodon*.

Four snakes were captured in Argentina in March, 1966. The adrenal glands were dissected into central and peripheral portions, and parts of each were sent to the United States for biochemical analysis. PNMT was assayed by methods described previously<sup>6</sup>, except that phenylethanolamine ( $3 \times 10^{-3}$  molar) was used as substrate, and the <sup>14</sup>C-N-methyl-phenylethanolamine formed enzymatically was extracted into a mixture of toluene and isoamyl alcohol (97:3). The assay depends on the transfer of a <sup>14</sup>C-methyl group from <sup>14</sup>C-S-adenosylmethionine to the amine nitrogen. The resulting radioactive product (*N*-methyl-phenylethanolamine) is separated from the labelled co-factor by extraction into the organic solvent at pH 10.

An average of  $9 \pm 2$  µmoles of *N*-methyl-phenylethanolamine was formed by peripheral

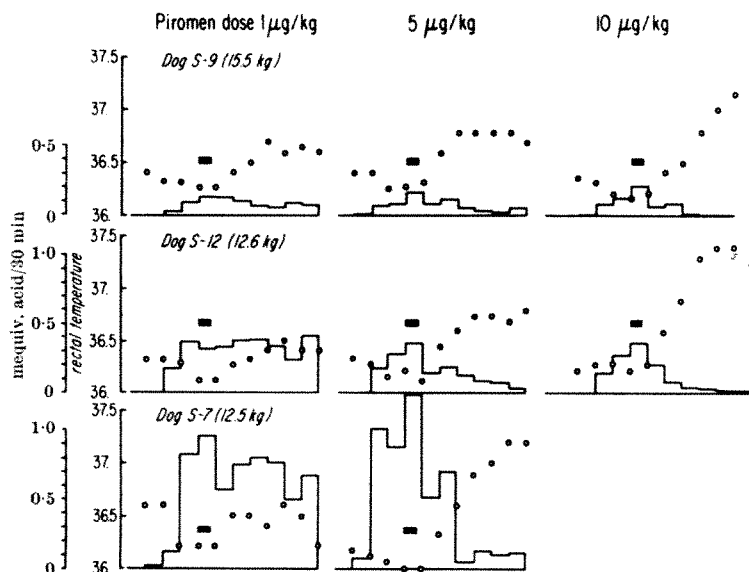

Fig. 1. Effect on acid secretion (solid line) of graded doses of 'Piromen' intravenously injected during the periods shown by black bars. The three dogs were stimulated to secrete from vagally denervated gastric pouches by infusion of histamine base (100 µg/h) beginning at the time of the first temperature recording and continuing till the end of the experiments. Rectal temperature recordings, represented by circles, were taken half-hourly. Dog S-7 was not subjected to the highest dose because 5 µg/kg appeared to cause unpleasant symptoms.

chromaffin tissue, while central tissues were able to synthesize  $104 \pm 28$   $\mu$ moles of the methylated product. Because only a small percentage of the cells in the central zone are chromaffin cells (most are cortical cells which produce steroids), it is likely that the concentration of PNMT in the central chromaffin cells is even greater than ten times that of the cells in the periphery.

Synthesis of adrenaline in the frog, *Rana pipiens*, is catalysed by a variant of mammalian PNMT, which has the same substrate specificity but different physical properties<sup>6</sup>. This enzyme does not appear to be controlled by adrenocortical steroids: unlike the mammalian enzyme its activity does not decline after hypophysectomy<sup>6</sup>. It is possible that snake PNMT is also independent of hormonal control, and that its high degree of localization in the chromaffin cells which are surrounded by cortical tissue is simply a coincidence. This hypothesis could be tested by determining whether central adrenal PNMT declines when the snake is hypophysectomized, or if the peripheral enzyme increases following treatment with large doses of glucocorticoids. A more likely explanation for the distribution of PNMT within the adrenal would be that in reptiles (like mammals, but unlike amphibians) this enzyme is under hormonal control. We suggest that all chromaffin cells in the snake adrenal are potentially able to make adrenaline but that they actually do so only after they have been stimulated chronically with large amounts of adrenocortical steroids.

### Atassi-Gandhi Sedimentation Coefficient and Molecular Weight Relationships

Atassi and Gandhi<sup>1</sup> have put forward empirical equations for the relationship of sedimentation constant to molecular weight for globular proteins. Their first equation was intended to cover molecular weights in the range 40,000–300,000 and the second had the tested range 12,000–30,000. Data for molecular weights of less than 12,000 were not given and both equations were reported to apply between 30,000 and 40,000. These equations are linear and I intend to show that they are chords to a more general relationship, well known to users of the ultracentrifuge, which relates sedimentation coefficient to molecular weight and is expressed by<sup>2,3</sup>

$$\frac{S[\eta]^{1/3}}{M^{2/3}} = 2.5 \times 10^6 \frac{(1 - \bar{v}\rho)}{\eta_s N} \quad (1)$$

Fig. 1. Plot of log sedimentation constant against log molecular weight. The straight line represents the least squares fitted value. A parabolic least squares did not give a significantly better fit.

where  $S$  is sedimentation coefficient (in Svedbergs),  $[\eta]$  is intrinsic viscosity,  $M$  is molecular weight,  $\bar{v}$  is partial specific volume of the solute,  $\rho$  is solvent density,  $\eta_s$  is solvent viscosity and  $N$  is the Avogadro number.

This equation can be rearranged to a good approximation

$$S = kM^{2/3} \quad (2)$$

or

$$\log S = \log k + \frac{2}{3} \log M \quad (3)$$

Variation in  $k$  is minimized by the use of the sedimentation constant,  $S_{20,w}$ , rather than the sedimentation coefficient, and therefore in testing the accuracy of equation (3), I used the sedimentation constant. The testing involved plotting  $\log S_{20,w}$  against  $\log M$  for a large number of proteins and viruses of  $f/f_0 < 1.30$  and molecular weights ranging from 17,000 to  $49 \times 10^6$  and extracting the slope and intercept by a least squares computer programme. The difference between the theoretical and experimental slopes was not statistically significant (Table 1) and so equation (3) becomes

$$\log S = 3.383 \pm 0.044 + \frac{2}{3} \log M \quad (4)$$

Table 1. THEORETICAL AND EXPERIMENTAL SLOPE AND INTERCEPT VALUES

	Theoretical	Experimental
Slope	0.667	$0.681 \pm 0.009$
Intercept	—	$-2.617 \pm 0.044$

The differences between the theoretical and experimental slopes are not significant at the 5 per cent level.

The equations of Atassi and Gandhi were then converted to a logarithmic form and superimposed on the fitted curve. Their lines (curved in the logarithmic form) lay around the least squares line, but had limitations in that they were only of use up to a molecular weight of 300,000 (as noted by Atassi and Gandhi) and that they were inapplicable at low molecular weights ( $< 9,000$ ). The areas where the equations did not apply lay outside the standard errors of the fitted line.

The limited application of the Atassi-Gandhi relationships can thus be attributed to the taking of chords to the plot of  $S_{20,w}$  against  $M$  and obviously these can only apply over a limited range which depends on the slope of the curve. Because the logarithmic plot is valid for a considerably wider range of molecular weights, and has a sound theoretical basis, it would seem more logical to use this relationship. It must be emphasized that these calculations are necessarily approximate because use of the constant  $k$  implies assumptions about uniformity of hydration, density, and shape. Nevertheless, the approxi-

mation is a good one, as can be seen from the closeness of the theoretical and experimental results, and reasonable values for molecular weights can be obtained.

### Influence of Urinary pH on the Excretion of Tranylecypromine Sulphate

URINARY pH is an important factor in determining the rate of excretion of amphetamine<sup>1-4</sup>. Tranylecypromine sulphate, an anti-depressant agent, is a related amine for which an assay procedure in urine has been developed<sup>5</sup>, based on its fluorescent properties. This method was at first thought to be only qualitative, but now has been found to be quantitative, and a linear relationship has been shown between fluorescent activity and concentrations of 0.1–4.0 µg/ml. of the drug in urine. Although tryptamine and tyramine reduced the fluorescence of tranylecypromine sulphate in certain concentrations, these were considerably higher than those found in the urine of patients treated with this drug. These amines did not therefore influence the assay procedure, and although it was possible to separate them from tranylecypromine sulphate the yield of this drug was not increased and separation therefore proved unnecessary (our unpublished observations).

Preliminary experiments in three patients given an oral dose of 20 mg of tranylecypromine sulphate ('Parnate') showed that the drug appeared in the urine within 2 h, with a maximum rate of excretion between 2 and 6 h, and disappeared after 12–16 h. The excretion of unchanged drug during the 24 h after administration was only between 1 and 5 per cent. Random urine samples were obtained from twelve patients receiving 10–20 mg of tranylecypromine sulphate daily. The drug was detected in all specimens, but only in amounts of less than 1 µg/ml., except in urine from a patient who had taken an unknown quantity of the drug 24 h before in a suicide attempt, where the concentration was 1.04 µg/ml.

In order to determine whether the excretion of unchanged tranylecypromine sulphate was dependent on the pH of urine, 20 mg was given in tablet form to four healthy subjects twice at weekly intervals. All urine passed during the next 16 h was collected at intervals of 2 h and the content of unchanged drug determined by a method described elsewhere<sup>5</sup>. On the first occasion, the pH of the urine was maintained at about 5.0 by the administration of ammonium chloride tablets before and during the experiment. On the second occasion, an alkaline urine (pH about 8.0) was maintained by giving sodium bicarbonate tablets before and during the experiment.

The results are given in Table 1, and the rates of excretion under both acid and alkaline conditions in one subject are shown in Fig. 1. They demonstrate that the unchanged tranylecypromine sulphate excreted in alkaline

Fig. 1. The cumulative excretion (µg) in one subject of unchanged tranylecypromine sulphate during a period of 16 h after administration of 20 mg by mouth, in acid (pH 5.0) and alkaline (pH 8.0) conditions.

urine after 16 h is only about 1 per cent of the dose, but is increased to about 8 per cent by acidification of the urine. Whereas the maximum rate of excretion under acid conditions was about 46 µg/min, it was only 0.26 µg/min under alkaline conditions. This bore no relationship to the volume of urine.

Despite this low yield of unchanged drug, the difference in rates of excretion suggests that it would be worthwhile to acidify the urine of patients who have taken an overdose of tranylecypromine sulphate. It is possible that the rates of excretion of some of its metabolites may also be increased in a similar way by acidification. If the patient is conscious, ammonium chloride tablets may be given and a 2 per cent solution of ammonium chloride may, with caution, be administered to the unconscious patient. In view of the toxicity of tranylecypromine, caution should be exercised when giving it to patients who may have a defect in urinary acidification, and in whom its action may therefore be increased and prolonged.

It is important to estimate the urine pH whenever the assay procedure for tranylecypromine sulphate is being carried out. If a doubtful result is obtained, ammonium chloride should be administered and the determination repeated when the urine is more acid.

The low yield of unchanged drug is interesting when compared with the relatively high yields of amphetamine under acid conditions<sup>1</sup>. To investigate the possibility that some tranylecypromine might be conjugated as a glucuronide, samples of urine from two patients receiving the drug, and a control urine containing no tranylecypromine were incubated with glucuronidase overnight at 37° C and analysed the next morning for tranylecypromine. Although there was a slight increase in the fluorescence of the control urine, there was a significantly greater increase in the readings from the urine of the patients after incubation with glucuronidase.

It appears therefore that only about 8 per cent of a dose of tranylecypromine sulphate is excreted in the unchanged form in 16 h, even under acid conditions, and that a further small amount may be conjugated as a glucuronide. These figures are consistent with the observations of Alleva<sup>6</sup>, who found that only 4 per cent of a dose of tranylecypromine labelled with carbon-14 was excreted in the rat. He also found that 12 per cent appeared as hippuric acid. There are several possible alternative pathways for metabolism, including cleavage

### Biliary Excretion of Aflatoxin in the Rat after a Single Dose

WHEN aflatoxin damages the liver<sup>1</sup> the cells most affected are those which are concentrated around the portal vein and bile duct. There seemed to be no published data on the quantitative pattern of biliary excretion of this toxin and the nature and partition of its metabolites in bile, and so we have investigated the problem.

Our experiments were made possible by the availability of aflatoxins B and G, labelled with carbon-14 in the uridine, and synthesized by a procedure developed here. The method involved the growing of spores of *Aspergillus flavus* in a Czapeck medium for 60 h before the addition to the culture of sodium acetate-2-<sup>14</sup>C. The product has a specific activity of 30 m $\mu$ c./mmole, and the method thus differs from the resting cell technique of Adye and Mateles<sup>2,3</sup>. A male rat weighing 350 g was lightly anaesthetized with ether before the establishment of a biliary fistula as described by Boyland *et al.*<sup>4</sup>. Bile was collected in a saddle-shaped container attached to the back of the rat by 'Elastoplast'<sup>5</sup>. In order to obtain samples of bile at regular intervals, a polythene tube was introduced into the chamber, and through this the bile was removed by suction. A dose of 50  $\mu$ g of labelled aflatoxin B<sub>1</sub> in saline with a specific activity of 30 m $\mu$ c./

mmole, was given by intraperitoneal injection to the rat and bile was collected every 15 min. A sample of bile (0.1 ml.) was transferred to a planchet, dried on a hot plate, and counted at infinite thinness in an end-window Geiger-Müller counter. The rate of excretion of labelled metabolites of aflatoxin B<sub>1</sub> in the bile is shown in Fig. 1.

There was a latent period of about 60 min between the time of injection and the first appearance of these metabolites in the bile samples collected. This was partly a result of the slow rate of flow of bile in the anaesthetized rat. It was, however, clear from the graph that aflatoxin was rapidly excreted through the bile, as was indicated by the observation of Falk *et al.*<sup>6</sup>. Aliquots of the 6 h collections of bile were shaken with equal volumes of chloroform for 20 min. The amounts of radioactivity in the chloroform layer were estimated as described earlier. The distribution of the counts in the various fractions is shown in Table 1.

Table 1. PARTITION OF LABELLED METABOLITES IN THE BILE SAMPLES OBTAINED FROM THE TREATED RAT

Time of collection	Total counts in bile samples (C-B)	Recovery of initial counts (per cent)		
		Total bile	CHCl <sub>3</sub> extract	Conjugates
0-6 h	13,800	30	10	20
6-12 h	770	1.7	0.7	1.0

C-B, counts in sample minus background counts.

Aliquots of the chloroform extracts were run on thin-layer chromatograms of silica gel G, using a mixture of 1 ml. of acetic anhydride; 2 ml. of methanol and 97 ml. of chloroform as the solvent. Each of these extracts contained a mixture of aflatoxin B<sub>1</sub> and aflatoxin M<sub>1</sub>, with similar properties to those described by other authors<sup>7-9</sup>. The principal constituent was a conjugate compound which gave a positive ninhydrin reaction on paper chromatography and was alkali labile. On alkaline hydrolysis of this conjugate, it yielded two fractions, one of which was identifiable with taurocholate on thin-layer chromatography, while the other had a slightly lower *R<sub>F</sub>* value than aflatoxin B<sub>1</sub> and gave a blue fluorescence in ultra-violet light. This last compound may have been a degradation product of aflatoxin B<sub>1</sub>. Work is in process with the aim of elucidating the nature of the aflatoxin bonding in the conjugate. Analysis of urine samples from the treated rat showed that approximately 26 per cent of the dose count was excreted as a glucuronide conjugate in the first 6 h after the injection of aflatoxin.

Our experiments with bile and urine suggest the existence of various pathways of aflatoxin B<sub>1</sub> metabolism in the rat, including that of demethylation proposed by Shank and Wogan<sup>10</sup>, who recovered 14-69.8 per cent of labelled aflatoxin in the faeces of four experimental rats, and Wogan<sup>11</sup> concluded from this that most of an aflatoxin dose was excreted through the bile. Our results show excretion of a glucuronide in the urine and of a taurocholate conjugate in the bile to be of great importance.

## Effect of Epinephrine on Insulin Release in Man induced by Secretin

SEVERAL observations taken together support the suggestion that the pancreatic  $\beta$ -cell responds in different ways to an oral glucose meal and to an intravenous infusion of glucose. (1) Oral glucose produces a greater rise in concentrations of plasma insulin than does an identical intravenous load<sup>1,2</sup>; (2) oral glucose provokes a response in plasma insulin four or five times greater than that achieved by infusing glucose intravenously to comparable concentrations of blood glucose<sup>3</sup>; (3) epinephrine blunts the release of insulin usually encountered after intravenous infusion of glucose<sup>4</sup>, but fails to suppress the rise in concentrations of plasma insulin which follows an oral glucose meal<sup>5</sup>.

In the light of these investigations, McIntyre *et al.* suggested that a gastrointestinal factor might allow the  $\beta$ -cell to discriminate between orally and intravenously administered glucose. Such a factor should initiate or augment the release of insulin from the pancreas, and its ability to stimulate the release of insulin should not be blocked by epinephrine.

Secretin has been shown to fulfil the first criterion. When it is intravenously administered, secretin elevates the concentration of portal venous insulin in man<sup>6</sup> and in the dog<sup>7</sup>. Perhaps of greater physiological significance is Dupré's observation that the rate of disappearance of an intravenous glucose load is accelerated by this compound<sup>8</sup>.

We report here that secretin also fulfils the second criterion: it produces an increase in plasma insulin in the face of a sustained infusion of epinephrine.

Four normal female subjects were investigated during the morning hours after an overnight fast. When control venous blood samples had been drawn, an infusion of epinephrine was commenced (4–8  $\mu\text{g}/\text{min}$ ). Forty-five minutes after the start of the infusion, an intravenous injection of 75 U of secretin (Vitrum, Ltd., Stockholm) was given, and venous blood samples were taken every 2 min throughout the next 10 min. Results are shown in Table 1 and a representative investigation is illustrated in Fig. 1. Plasma insulin was measured by the radioimmunoassay technique of Yalow and Berson<sup>9</sup> and plasma glucose by the glucose oxidase method. During the initial period of epinephrine infusion, the concentrations of plasma insulin did not change appreciably from those

before infusion, despite significant elevations in the concentration of plasma glucose in all four subjects (average rise 51.6 mg/100 ml.; range 37.0–70.5 mg/100 ml.). When secretin was administered, concentrations of plasma insulin rose in all four subjects (average rise 28.5  $\mu\text{U}/\text{ml}$ .; range 5–52  $\mu\text{U}/\text{ml}$ .). The greatest increases occurred at 2 min and they rapidly fell to approach pre-injection levels within 10 min. When the infusion of epinephrine was discontinued all subjects showed a marked rise in plasma insulin values which were greatest at 10–30 min.

\* These values are significantly different from those before the secretin was administered at time 45 min ( $P < 0.05$ , by paired analysis).

75 U of secretin was injected at time 45 min in four normal fasting female subjects who were receiving an infusion of epinephrine (4–8  $\mu\text{g}/\text{min}$ ) commenced at time zero. The last column shows the highest concentration of plasma insulin achieved following discontinuation of the epinephrine infusion.

Two subjects were investigated with an identical dose of secretin when hyperglycaemia was produced by infusion of 300 mg of dextrose/min. Concentrations of plasma glucose rose to 47.9 and 46.5 mg/100 ml., and those of plasma insulin increased 19 and 9  $\mu\text{U}/\text{ml}$ ., respectively, after 45 or 80 min, at which time they were given an identical dose of secretin as in the epinephrine experiment. Concentrations of plasma insulin promptly rose, reaching a peak at 4 min, which represented a further rise of 25 and 26  $\mu\text{U}/\text{ml}$ ., and rapidly fell thereafter.

Using the same batch of Vitrum secretin we were unable to find a significant rise in concentrations of peripheral plasma insulin after intravenous injection of secretin to four normal female subjects, including three of the four referred to earlier, investigated in the basal fasting state (Table 2). This contrasts with the unequivocal rise in the concentration of plasma insulin produced by the same dose of secretin when hyperglycaemia had been produced by epinephrine (even though the hyperglycaemic state itself did not augment the concentration of plasma insulin because of epinephrine-blockage of insulin release) or by infusion of dextrose. These findings point toward a regulating device which may ensure that release of insulin is fully augmented by secretin only in appropriate circumstances (for example, postprandial hyperglycaemic states). However, we wish to emphasize the variations in insulinogenic potency between different batches of secretin. Some Jorpes secretin preparations do elevate plasma insulin levels, even in the normoglycaemic state, as already reported by Dupré *et al.*<sup>6</sup>.

Table 2. CONCENTRATIONS OF PLASMA INSULIN ( $\mu\text{U}/\text{ml}$ .) AFTER INTRAVENOUS INJECTION OF 75 U OF SECRETIN AT TIME ZERO IN FOUR NORMAL FASTING FEMALE SUBJECTS WITH NO PRETREATMENT

The effects on the release of insulin of several other gastrointestinal factors have been explored and of these glucagon has perhaps been most thoroughly investigated<sup>10–12</sup>. It is of interest that whereas glucagon undoubtedly initiates release of insulin from the pancreas, this effect is reported to be blocked by epinephrine<sup>4</sup>.

In summary, secretin can, in the presence of hyperglycaemia, cause a significant elevation in concentrations

Fig. 1. Changes in concentrations of plasma glucose and insulin in a normal female subject (B. F.) after injection of 75 U of secretin 45 min after commencement of an infusion of epinephrine (5.1  $\mu\text{g}/\text{min}$ ). The rise in concentrations of plasma insulin after discontinuation of the epinephrine is also well shown.

of plasma insulin. This effect is not inhibited by epinephrine, an agent which blocks the release of insulin observed after intravenous administration of glucose. Secretin thus fulfils the requirements as a mediator of the mechanism which produces the augmented secretion of insulin observed after oral, as compared with intravenous, administration of glucose.

### Concentration of Glucose in New Choroidal Cerebrospinal Fluid of the Rabbit

It is characteristic of mixed cerebrospinal fluid, sampled in the steady state, that the concentration of glucose is deficient compared with plasma. Yet the fluid appears grossly to be neither a source nor a sink in relation to the sugar in the brain because regional differences in concentration have not been disclosed by successive sampling<sup>1</sup>, or by analyses of fluids taken from several sites<sup>2</sup>. In unsteady conditions after elevation of plasma glucose<sup>3</sup>, or during ventriculo-cisternal perfusion with an initially glucose free solution<sup>4</sup>, the flow of glucose into the system is by a facilitated mechanism and at a rate faster than could be accounted for by the contribution through choroid plexuses. Thus the concentration of glucose in fluid might be rapidly imposed by the brain if new fluid were formed with a composition different from that of mixed fluid.

The extent to which the choroid plexuses contribute to the maintenance of the deficiency of glucose was investigated by applying the enzyme method of Lowry *et al.*<sup>5</sup> to its analysis in arterial plasma, a filtrate of plasma and new choroidal fluid sampled by the method of de Rougemont *et al.*<sup>6</sup>.

After anaesthesia with sodium pentobarbitone 40 mg/kg, supplemented when necessary, the concentration of glucose in plasma invariably rose. The mean increase was by a factor of  $1.79 \pm 0.15$  (mean  $\pm$  standard error of the mean, eighteen animals). The hyperglycaemia was very resistant to insulin but was prevented by 2 mg of pentalonium lactate, 1-2 h before induction of anaesthesia. It seems likely that the glycogenolysis is mediated through

Table 1. VALUES FOR THE RATIO CONCENTRATION OF GLUCOSE IN NEW CEREBROSPINAL FLUID : CONCENTRATION IN PLASMA, GROUPED FOR DIFFERENT RANGES OF PLASMA CONCENTRATION

Range of plasma concentration (mmolar)	No. of observations	Mean ratio $\pm$ standard error of the mean
0-8	10	$0.589 \pm 0.015$
8-11	27	$0.589 \pm 0.018$
11-13	34	$0.601 \pm 0.013$
13-15	15	$0.594 \pm 0.020$
15-20	28	$0.519 \pm 0.018$
20-30	30	$0.464 \pm 0.019$
30-40	21	$0.477 \pm 0.013$
>40	13	$0.457 \pm 0.023$

hypothalamic release associated with cortical depression by anaesthesia. The concentration in a filtrate was  $0.98 \pm 0.015$  that of plasma (eighteen observations).

The results of the study are presented in Fig. 1 in which the ratio, concentration of glucose in new fluid : concentration in plasma, is plotted against plasma concentration. Below modestly elevated plasma concentrations (<15 mmolar) the mean ratio was  $0.596 \pm 0.010$  (mean  $\pm$  standard error of the mean, eighty-six observations). When the concentration in plasma was greater than 15 mmolar the ratio was decreased as concentration in plasma was increased. By grouping the observations (Table 1) we found that the change to smaller ratios was rather abrupt between 15 and 20 mmolar in plasma. For less than 15 mmolar in plasma the slope of the calculated best line was virtually zero. For a concentration in plasma of more than 20 mmolar, the mean ratio was  $0.467 \pm 0.018$  (mean  $\pm$  standard error of the mean, sixty-four observations) while the calculated slope was again virtually zero. In Fig. 1b the calculated best lines and 95 per cent confidence limits of the slopes are shown.

The results indicate that at least two processes are involved in the transport. An analysis of the kinetics promises to be difficult and will require further examina-

Fig. 1. (a) The ratio, concentration of glucose in new choroidal cerebrospinal fluid : concentration in arterial plasma is plotted against plasma concentration. The variations in plasma concentration were spontaneous and brought about by insulin and/or infusion of glucose. (b) The calculated best lines and the 95 per cent confidence limits for the slopes are shown. The calculated slopes are, for the segment below 15 mmolar,  $5 \times 10^{-4}$ ; for the segment above 20 mmolar,  $2 \times 10^{-4}$ ; and for the intermediate segment which is calculated for points between 14 and 21 mmolar, it is  $-0.022$ .

tion of the behaviour in individual animals and the study of other sugars.

That the new fluid is secreted at approximately the same concentration of glucose relative to plasma as has been measured for mixed fluid in the steady state<sup>7</sup>, shows that in steady conditions the sugar of the fluid enters with the volume inflow. The observation that mixed fluid in the steady state is neither a source nor a sink in relation to the brain<sup>2</sup>, is therefore not explained by a rapid and thus unobserved equilibration between the two compartments. On the other hand, exchange between the two is rapid and, in unsteady conditions, flow of sugar between parenchyma and cerebrospinal fluid is important.

The concentration of glucose in the cerebrospinal fluid is thus doubly controlled, during its secretion and by its relationship with the brain.

### Specific Activity of Carbon Dioxide expired by Rats after Oral Sucrose and Other Sugars

A COMPARISON of the rates at which the respiratory quotient (RQ) rises after various sugars are given by mouth to human beings or dogs suggests that sucrose is more rapidly metabolized than either glucose or fructose, or a mixture of these monosaccharides<sup>1-4</sup>. Nevertheless, the interpretation of the RQ is not unequivocal. In a more direct investigation of the rates at which oral sucrose, glucose and fructose and certain other sugars are metabolized, sugars labelled with radioactive carbon were fed to rats and the comparative rates at which radioactive carbon dioxide was expired were determined. The radioactive sugars were obtained from the Radiochemical Centre, Amersham, except labelled maltotriose, which was prepared by one of us (A. F. M. M.) by hydrolysing radioactive starch and separating by charcoal adsorption and chromatography on paper.

Solid sugar was fed to the rat in a gelatine capsule which, unless otherwise stated, contained 50 mg of unlabelled and 0.5  $\mu$ c. of <sup>14</sup>C(U) labelled sugar. Samples of the expired air were then collected during consecutive 20 min periods for 1-4 h. The expired carbon dioxide was collected in L-M-hyamine solution in methanol, the total carbon dioxide being determined by titration with 0.1 normal hydrochloric acid in triplicate under nitrogen<sup>5</sup>. Radioactivity present was measured on a liquid scintillation spectrometer, with a non-aqueous scintillator<sup>6</sup>. The specific activity of the expired carbon dioxide was expressed as c.p.m./mmole expired carbon dioxide.

A comparison of the specific activity of the carbon dioxide expired after the oral administration of sucrose-<sup>14</sup>C to a group of ten rats with that after oral glucose-<sup>14</sup>C is shown in Fig. 1. A significantly greater rise ( $P < 0.001$ ) in the specific activity of the expired carbon dioxide was observed during the first 20 min after oral sucrose than after oral glucose. This difference decreased with time, and had disappeared after 1 h. These results agree with

Fig. 1. The vertical lines through each point represent the standard error of the mean value. In each instance a total of 50 mg of sugar was fed, the radioactivity being 0.5  $\mu$ c. A, Sucrose; B, glucose.

Fig. 2. In each instance a total of 50 mg of sugar was fed, the radioactivity being 0.5  $\mu$ c. A, Sucrose; B, glucose; C, fructose; D, glucose plus fructose.

Fig. 3. In each instance a total of 50 mg of sugar was fed, the radioactivity being 6,000 c.p.m. A, Sucrose; B, glucose; C, maltotriose.

the interpretation of earlier workers that oral sucrose is more rapidly metabolized to yield carbon dioxide in the animal body than is oral glucose.

Fig. 2 shows the comparative effects of oral sucrose, glucose, fructose and an equimolecular mixture of glucose

and fructose on the specific activity of the expired carbon dioxide. Oral sucrose produces a greater increase in the specific activity of the expired carbon dioxide than any of the other sugars.

The specific activities of expired carbon dioxide observed after the administration of 50 mg of a number of sugars, namely, sucrose- $^{14}\text{C}$ , glucose- $^{14}\text{C}$  and maltotriose- $^{14}\text{C}$ , to a single rat are compared in Fig. 3. The activity of labelled sugar fed in each instance was about 6,000 c.p.m. The results with oral maltotriose- $^{14}\text{C}$  are similar to those obtained with sucrose- $^{14}\text{C}$ , and the specific activity of the expired carbon dioxide after oral administration of these sugars is considerably greater than that seen after feeding glucose- $^{14}\text{C}$ .

These results support the earlier conclusions of others obtained by different methods that the metabolism of oral sucrose begins more rapidly than that of oral glucose or fructose. The metabolic reason for this interesting difference remains to be investigated.

We thank Professor W. J. Whelan, Department of Biochemistry, Royal Free Hospital Medical School, London, for a gift of pure maltotriose, and the Medical Research Council for a grant which supported one of us (A. F. M. M.) during this investigation.

### Adenosine Triphosphatase activated by Magnesium and Superprecipitation of Myosin B

THE importance of the divalent cations calcium and magnesium in muscle contraction is widely acknowledged<sup>1,2</sup>. An ordinary preparation of myosin B has been found to contain the "extra proteins" which are responsible for the effects of calcium on the magnesium-activated superprecipitation and adenosine triphosphatase (ATPase)<sup>3,4</sup>. As to the effects of magnesium, however, it is not clear whether this ion acts directly on the protein or indirectly by forming a complex with ATP<sup>5</sup>. How the activity of ATPase is related to the superprecipitation is still not known. We have attempted to ascertain the relationship of the two functional properties of myosin B by observing the effects of magnesium ions on the behaviour of the protein which shows no sensitivity to calcium.

Myosin B was prepared from rabbit skeletal muscle by the method of Perry *et al.*<sup>4</sup>. In order to minimize the influence of potassium chloride on the properties of myosin B and not to complicate the ionic species in test solution, the concentration of potassium chloride was kept at 5 mmolar. The contamination of magnesium ions in the test system could not be avoided even when the reagents were treated with 'Dowex 50' (potassium ion form), and so ethylenediamine tetraacetic acid (EDTA) was added to the system to observe the effect of the smallest possible concentration of free magnesium<sup>6,7</sup>. The rate of superprecipitation was determined by the method described by Levy and Fleisher<sup>8</sup>. In the conditions of the experiment, the turbidity of the suspension of myosin B increased about thirteen times with the addition of ATP, and the extent of the increase was fairly constant (deviation  $\pm 10$  per cent of average), except at the concentration of free magnesium ions of less than  $5 \times 10^{-5}$  molar, where ATP is exhausted before completion of the change in turbidity. The activity of ATPase in the steady state was measured

Fig. 1. Effects of magnesium ions on the rates of ATP hydrolysis and superprecipitation of myosin B. A relative rate of ATP hydrolysis (○) of 100 is equivalent to the activity of 0.12  $\mu\text{moles/mg}$  of myosin B/min. A rate of superprecipitation (●) of 100 corresponds to a turbidity change of 0.18/sec (2 cm light path). Reaction mixture: 5 mmolar potassium chloride, 1 mmolar EDTA, 20 mmolar *tris* (pH 7.4), 0.1 mmolar ATP, 0.056 mg of myosin B/ml., and magnesium chloride was varied. Temperature, 25° C. The curve marked MgATP represents the formation of magnesium-ATP complex with the concentration of free magnesium. This curve was calculated according to ref. 9.

by the assay of inorganic phosphate and by pH-stat. The two methods of ATPase analysis were consistent with one another. In Fig. 1 the activity of ATPase and the rate of superprecipitation are plotted against the concentration of free magnesium ions which was calculated as described by Botts *et al.*<sup>9</sup>. We assumed that the total concentration of magnesium consists of those of free magnesium ions,  $\text{MgATP}^-$ , and the complexes of magnesium and EDTA. Each of the experimental curves represented the simple relationship of binding reaction between magnesium ions and a ligand, which was assumed to be myosin B. The apparent dissociation constants were estimated as  $4.5 \times 10^{-6}$  molar<sup>10</sup> for the ATPase curve and  $1.6 \times 10^{-4}$  molar for the superprecipitation. Although there is a region of magnesium concentration where the increase in the rates appears to parallel the formation of  $\text{MgATP}^-$ , the binding of magnesium ions to the protein is apparently responsible for the full activation. The curves of the same type as those in Fig. 1 were obtained with various concentrations of ATP from 0.01 mmolar to 0.1 mmolar. The maximum rates of both ATPase and superprecipitation at varied concentrations of ATP resulted in the curve shown in Fig. 2. The omission of EDTA, in the presence of 5 mmolar magnesium chloride, did not affect the results of Fig. 2. The curve follows the

Fig. 2. Change in the rates of ATP hydrolysis and superprecipitation with the concentration of ATP. A relative rate of ATPase (○) of 120 is 0.12  $\mu\text{moles}$  of ATP hydrolysed/mg of myosin B/min. A relative rate of superprecipitation (●) of 120 corresponds to a turbidity increase of 0.18/sec. Reaction mixture contained 5 mmolar potassium chloride, 1 mmolar EDTA, 20 mmolar *tris* (pH 7.4), 5 mmolar magnesium chloride, 0.056 mg of myosin B/ml., and varied concentration of ATP. Temperature, 25° C. The rates of ATPase and superprecipitation in the presence of 5 mmolar magnesium chloride were observed to be maximal at each fixed concentration of ATP.

kinetic formula of the Michaelis-Menten type with the value of  $K_m$  as  $5 \times 10^{-5}$  molar.

Magnesium affects independently the activity of ATPase and the rate of superprecipitation, which suggests that these two effects are not closely related in this respect, whereas the changes in the rates of both functions with the concentration of ATP are parallel to each other. If this parallelism should be an indication of direct coupling of the two functions, the fact that the relationship between the rates and the concentration of ATP follows the Michaelis-Menten kinetics would have some significance. If the value of  $K_m$  represents a dissociation constant of the binding reaction between ATP and myosin *B*, the simplest mechanism which involves the binding of ATP at one site on the protein can be proposed. There are possibly two different types of sites for ATP binding: one for the hydrolysis of ATP and the other for the physical change of protein, with the same affinity to ATP in the experimental conditions. If the value of  $K_m$  for either one or both functions cannot be regarded as the dissociation constant, the same value of  $K_m$  for the two processes appears to be coincidental and no simple explanation for the parallelism can be offered at the moment.

Levy and Fleisher<sup>11</sup> suggested that superprecipitation requires the concerted action of ATP or ITP at two or more sites on the protein complex. These authors determined the rates of superprecipitation in 0.06 molar *tris* buffer (pH 7.4) with 0.03 molar potassium chloride and 5 mmolar magnesium chloride. Our experiments in the same ionic conditions reproduced the curve shown in Fig. 2. The difference between the results reported by Levy and Fleisher<sup>11</sup> and those presented here can be attributed to the extra protein factors, because the preparation of myosin *B* that has not been washed by distilled water shows the results obtained previously. It could be argued that the lack of direct correlation between the rate of superprecipitation and the activity of ATPase observed with natural actomyosin or in certain ionic conditions could result from factors such as ions and extra proteins acting on the specific site(s) that may be involved differently in ATP hydrolysis and superprecipitation.

### Enzyme Mechanism of Aminoacetone Metabolism by Micro-organisms

ALTHOUGH aminoacetone was first recognized as a microbial metabolite in 1958 (ref. 1), and found to be formed from L-threonine<sup>1-5</sup>, glycine plus a source of acetyl-CoA<sup>1,2,4,5</sup>, or isopropanolamine<sup>5,6</sup> (1-aminopropan-2-ol) by a variety of micro-organisms, it has only recently been found that the amino ketone is further metabolized

Fig. 1. Effect of the concentration of NAD on the formation of aminoacetone from L-threonine in the presence of 2-oxo acids or malate. Reaction mixtures contained 125 mmolar *tris* buffer (pH 8.5), 400 mmolar potassium chloride, 25 mmolar L-threonine, 2 mmolar 2-oxoglutarate (O), oxaloacetate (Δ) or D,L-malate (●), NAD as shown, 0.1 mg *B. subtilis* cell free extract/ml. Controls were reaction mixtures from which 2-oxo acids or malate were omitted. Incubation was for 10 min at 37° C. The formation of aminoacetone was measured as previously described<sup>4</sup>.

by resting cell suspensions of some bacteria<sup>7</sup>. The rapid utilization of aminoacetone by extracts free from cells has now been demonstrated and information of the enzyme mechanism of aminoacetone metabolism is available.

During a study of the activity of L-threonine dehydrogenase in cell free extracts of *Bacillus subtilis*, grown on nutrient broth, we observed that the accumulation of aminoacetone was inhibited by 2-oxoglutarate, oxaloacetate or D,L-malate. The inhibitory effect of these compounds was marked when nicotinamide adenine dinucleotide (NAD) was present at high concentrations (see Fig. 1), but was completely absent when partially purified preparations of L-threonine dehydrogenase were used. Similar results were obtained when aminoacetone formation was measured during studies of L-1-aminopropan-2-ol dehydrogenase<sup>6</sup> activity. It appeared likely that 2-oxo acids facilitated the further metabolism of the amino ketone and that NAD was also required. This was found to be so using synthetic aminoacetone, and the rate of its utilization by an extract of *B. subtilis* was found to be about 27 μmoles/mg protein/min at 37° C in the system: 125 mmolar *tris*-HCl buffer (pH 8.5), 400 mmolar potassium chloride, 20 mmolar 2-oxo-glutarate, 10 mmolar NAD, 0.125 mmolar aminoacetone and 0.14 mg extract protein/ml. Additional results showed the  $K_m$  for aminoacetone in this system to be about 2.0 mmolar, the optimum activity to be at about pH 10, and that potassium chloride was not required. Maximum rates of about 40 μmoles aminoacetone utilized/mg protein/min at 37° C have been observed.

High rates of utilization of aminoacetone have been observed when cell free extracts of *Pseudomonas* sp. NCIB 8858 are grown on D,L-1-aminopropan-2-ol (ref. 7). Rates of utilization of aminoacetone of about 120 μmoles/mg protein/min at 30° C were found with the system: 60 mmolar potassium phosphate buffer (pH 7.5), 20 mmolar 2-oxoglutarate, 20 mmolar NAD, 0.1 mmolar pyridoxal phosphate, 1 mmolar aminoacetone, 1.0 mg extract protein/ml. At the pH optimum of 7.5, with saturating concentrations of aminoacetone and 2-oxoglutarate, the half-maximum velocity of aminoacetone

disappearance occurred when the concentration of NAD was about 1 mmolar. The  $K_m$  values for 2-oxoglutarate and aminoacetone were similarly found to be about 2 mmolar, and 1 mmolar, respectively. Both oxaloacetate and pyruvate could replace 2-oxoglutarate without marked reduction of activity, and 2'-aminoacetophenone but not 5-aminolevulinate was utilized as rapidly as aminoacetone. The activity of the system utilizing aminoacetone was strongly inhibited by common sulphhydryl reagents, metal-chelating agents and some carbonyl reagents. Methylglyoxal inhibited activity by 50 per cent at 0.25 mmolar and completely at about 1.0 mmolar. The activity of dialysed extracts was increased by a factor of two by the addition of magnesium ions at 2 mmolar.

The results obtained with both *B. subtilis* and the *Pseudomonas* sp. are consistent with an enzyme mechanism for the utilization of aminoacetone involving a coupled aminoacetone-2-oxoacid aminotransferase and 2-oxo-aldehyde-NAD oxidase<sup>8,9</sup> system. The latter enzyme has been studied in extracts of the pseudomonad and found to be distinct from a D-lactate dehydrogenase also present at lower levels of activity. It would seem that methylglyoxalase activities are not involved in methylglyoxal metabolism by cell free extracts. The properties of the presumptive aminoacetone aminotransferase are at present under investigation, but this is complicated by the obligatory requirement for the oxoaldehyde oxidase to prevent any accumulation of the inhibitory product methylglyoxal. No 2-oxo-aldehyde aminotransferase activity with methylglyoxal plus a variety of amino group donors could be detected by assays for aminoacetone formation.

Preliminary results suggest that a number of micro-organisms other than those mentioned here are capable of metabolizing aminoacetone by way of methylglyoxal.

## Action of Thyrocalcitonin in the Teleost Fish *Ictalurus melas*

HORMONAL control of calcium homeostasis in the lower vertebrates has received relatively little attention. This is particularly true for teleost fish in which there is a definite osseous skeleton but no parathyroid glands. Understanding of control of calcium homeostasis in these animals therefore is a problem of considerable evolutionary and physiological interest. The demonstration of a potent hypocalcaemic factor in the thyroid tissue of certain mammals<sup>1</sup> has now provided a new approach, because teleost fish possess definite thyroid follicles in spite of their diffuse occurrence. We have examined the effects of a porcine thyrocalcitonin extract on concentrations of

serum calcium and phosphate in the catfish and tried to demonstrate the presence of thyrocalcitonin in catfish tissue which contained thyroid follicles.

We designed an experiment to examine the effects of increasingly large doses of the extract on serum calcium and phosphate. Twenty catfish were given randomly four treatments consisting of an acid saline (pH 4) control and three different doses of porcine thyrocalcitonin extract—0.2 ml., 0.5 ml. and 2.0 ml. The extract was prepared as described before<sup>2</sup>. The average weight and length of the fish were 150 g and 23.2 cm. The fish were maintained in large aerated aquaria, filled with water from the river where they had been caught. The pH of this water was 5.8 and the average temperature during the course of the experiment was 25.3° C. The extract was administered intraperitoneally, the fish were bled by heart puncture 60 min after injection, and serum calcium<sup>3</sup> and phosphate (using a modification of the method of Fiske and Subbarow<sup>4</sup>) were determined. The results are summarized in Table 1. Not all blood samples were considered to be large enough for accurate analysis and, where applicable, this is reflected in the reduced number of animals in each treatment group shown in Table 1.

The results in Table 1 show a progressive hypocalcaemia with increasing doses of thyrocalcitonin extract. This stepwise reduction in serum calcium is statistically significant, as indicated in Table 1. The data also show a marked and highly significant hypophosphataemic effect of the extract with maximum response recorded with a dose of 0.5 ml. These responses in the catfish are qualitatively similar to those in the rat<sup>5</sup> and the dog<sup>6</sup>.

Table 1. EFFECT OF INCREASING DOSAGE OF PORCINE THYROCALCITONIN ON SERUM CALCIUM AND PHOSPHATE IN THE CATFISH

Treatment	No. of animals	Serum calcium (mg/100 ml.)		No. of animals	Serum phosphate (mg/100 ml.)

\* Significantly different from saline control ( $P < 0.05$ ).

† Significantly different from saline control ( $P < 0.02$ ).

‡ Significantly different from saline control ( $P < 0.01$ ).

In a second experiment, we tried to demonstrate the presence of a hypocalcaemic factor in catfish tissue which contained thyroid follicles. For this purpose a section of connective tissue measuring approximately 2 cm × 5 mm × 5 mm was removed on both sides of the ventral aorta, immediately anterior to the heart, from thirty fish. Microscopic examination of samples of this tissue confirmed the presence of thyroid follicles, but the dispersion of the follicles was rather diffuse. A crude extract of this tissue was prepared by the method of Stahl *et al.*<sup>2</sup>; the supernatant fluid from the low speed centrifugation was used. The extract was then assayed for any hypocalcaemic or hypophosphataemic properties by injecting it into five rats subcutaneously in a dose of 0.6 ml. (equivalent to 120 mg of fresh tissue) to each animal. Serum calcium and phosphate were determined 60 min after injection and compared with a similar control group which had received injections of 0.6 ml. of 0.1 normal hydrochloric acid. The results showed no significant effect of the extract on either serum calcium or phosphate. The serum calcium concentrations remained unchanged at 10.0 mg/100 ml. and the serum phosphate was only slightly depressed from 9.4 to 8.9 mg/100 ml. These results are not considered conclusive in any way, because the diffuse dispersion of the thyroid follicles may require a larger dose to elicit a response. Furthermore, the polypeptide nature of thyrocalcitonin may mean that species specificity is involved in inhibiting the interspecific action of this hormone in certain cases.

Our results have shown that a teleost fish is very responsive to the action of mammalian thyrocalcitonin. This fact in itself is of evolutionary and pharmacological interest and confirms the desirability of pursuing this approach to solve problems of hormonal control of calcium homeostasis in teleost fish.

### Lysozyme and the Pericapillary Reticulin Network

We have previously observed a heterogeneity in the carbohydrate fraction of human reticulin fibres and basement membranes. This heterogeneity seemed to be related to the biological age of the subject, the age of the network, the metabolic characteristics of certain organs and tissues and the functional dynamics of various cellular groups<sup>1,2</sup>. In a further investigation of the mechanisms of silver impregnation, which will be described in a later publication, we made many enzyme digestions (sialidase, lysozyme, pectinase,  $\alpha$ -amylase,  $\beta$ -glucuronidase, bacterial and testicular hyaluronidase, ribonuclease, pepsin, trypsin, papain and collagenase). During this investigation a peculiarity was revealed after incubation with lysozyme of the samples fixed in Carnoy solution. In the sections treated for 48 h at 37° C with lysozyme (Worthington Biochemicals Corporation, twice crystallized 5 mg/30 ml. of 0.2 molar phosphate buffer, pH 5.3 (ref. 3)) there was a constant disruption and dislocation of the

Fig. 1. Human liver. Lysozyme digestion followed by Gomori's silver impregnation. Dislocation of the pericapillary (perisinusoidal) reticulin network. ( $\times$  c. 585.)

Fig. 2. Human liver. Lysozyme digestion followed by Gomori's silver impregnation. Dispersed reticulin network exhibiting an intense and homogeneous affinity for silver impregnation. Many of the dispersed filaments end in a closed loop. ( $\times$  c. 150.)

Fig. 3. Human spleen. Lysozyme digestion followed by Gomori's silver impregnation. Dislocation and dispersion of the reticulin network exhibiting aspects of fibrillary balls. ( $\times$  c. 585.)

pericapillary (or perisinusoidal) reticulin network (Figs. 1-4). These aspects have not been seen in control slides incubated in an inactivated lysozyme by Lugol's iodine 1:300 buffer<sup>3</sup> or in the buffer solution. Of all the glycolytic and proteolytic enzymes used, lysozyme alone could bring about this process. If the incubation with lysozyme was preceded by digestion with another enzyme, the changes occurred with the same intensity as those observed with lysozyme alone.

As a consequence of the disruption and dislocation brought about by digestion with lysozyme, fragments of the reticulin network, balls of fibre and isolated fibres were detached from the capillary bed and randomly distributed throughout the whole section. Many of the dispersed filaments were terminated by a closed loop. They exhibited a more homogeneous and more intense affinity for silver impregnation when compared with the untreated pericapillary reticulin network in the control slides. On the other hand, the material located between the pericapillary reticulin network and the endothelial layer, which can be shown by both silver impregnation and the periodic acid-Schiff technique to be an apparent basement membrane, seemed not to be modified by lysozyme digestion.

This process of disruption, dislocation and dispersion of the pericapillary reticulin network determined by the action of lysozyme, was constantly found in human liver (Figs. 1 and 2), spleen (Fig. 3), lungs (Fig. 4), myocardium and kidney, both with Gomori's silver impregnation and McManus periodic acid-Schiff reaction.

Fig. 4. Human lung. Lysozyme digestion followed by Gomori's silver impregnation. Disrupted filaments of the pericapillary reticulin network of the alveolar wall. ( $\times c. 585$ .)

Lysozyme is a  $\beta$ -glucosaminidase which acts on *N*-acetylated glucosamines in oligosaccharides, hydrolysis  $\beta$ -glycosidic bonds connecting *N*-acetyl glucosamine with other components<sup>4</sup>. The presence of glucosamine in reticular tissue has been mentioned by several authors<sup>2,4,7</sup>. Our results suggest that glucosamine is included in a complex of "cement substances" which connects the pericapillary reticulin network to the sub-endothelial space, structurally organized as an apparent basement membrane. Our results also suggest that glucosamine is a component of the perifibrillar sheet of the reticulin fibre, the elimination of which unblocks chemically and/or sterically some reactive groups, allowing more intense and uniform impregnability with silver nitrate of the dislocated and disrupted network.

Thus there is the possibility of a deeper understanding of the mechanisms which control the visco-elastic resistance of the capillary wall and of the agents which may influence its adequate adaptation to local haemodynamic and metabolic peculiarities.

In conclusion, these data are consistent with the assumption that a material susceptible to lysozyme (probably glucosamine) is included in a "cement" complex which connects the pericapillary reticulin network to the sub-endothelial space, and is organized as an apparent basement membrane.

### Isolation of an L-Fucose Binding Protein from *Lotus tetragonolobus* Seed

Morgan and Watkins<sup>1</sup> have shown that haemagglutination of group O human red blood cells by an aqueous extract of *Lotus tetragonolobus* seed is inhibited by L-fucose but not by D-fucose. In this communication we describe the isolation from *L. tetragonolobus* of a protein which binds specifically L-fucose and which agglutinates group O human red blood cells. The isolation is based on specific

precipitation of the L-fucose binding protein by a dye containing three  $\alpha$ -L-fucopyranosyl residues. The trifunctional fucosyl dye (1,3,5-tri-(*p*- $\alpha$ -L-fucosyloxyphenylazo)-2,4,6-trihydroxybenzene) was prepared from *p*-aminophenyl  $\alpha$ -L-fucopyranoside<sup>2</sup> by diazotization and coupling to phloroglucinol in a manner similar to some other trifunctional glucosyl dyes<sup>3</sup>. The isolated protein is characterized in terms of its molecular weight and its L-fucose binding isotherm.

Freshly milled seed (weighing 100 g) marketed as 'Asparagus pea' by Thompson and Morgan, Ltd., Ipswich, England, was extracted with a cold salt solution (2-3 l. of 0.85 per cent sodium chloride, 0.02 molar phosphate, pH 6.8 with sodium hydroxide) by stirring for 3 min in a homogenizer immersed in an ice bath. The cleared extract was fractionated by addition of solid ammonium sulphate, first to 30 per cent, then to 60 per cent saturation. The precipitate that formed between 30 per cent and 60 per cent saturation (4° C overnight) was collected and extracted with the salt solution (100 ml. for 100 g of flour). Trifunctional glucosyl dye (1,3,5-tri-(*p*- $\beta$ -D-glucosyloxyphenylazo)-2,4,6-trihydroxybenzene)<sup>3</sup> was added to the clarified extract (50  $\mu$ g/ml.) to precipitate a polysaccharide present in the extract that interferes with the specific precipitation of the L-fucose binding protein by the fucosyl dye. After standing overnight at 4° C, the red precipitate was removed by centrifugation and the fucosyl dye was added to the supernatant to a final concentration of 50  $\mu$ g/ml. The red precipitate that formed (4° C overnight) was collected, washed twice with cold salt solution and then extracted with a cold 2 per cent solution of L-fucose. The dye was removed by treatment with ion exchange resin (AG1-X4, Bio-Rad Laboratory, Richmond, California) equilibrated with the L-fucose solution. After a few hours of dialysis at room temperature against a few changes of salt solution to remove most of the L-fucose, the protein was precipitated by addition of fucosyl dye. The precipitate was washed, dissolved and freed of the dye as before. The protein was dialysed exhaustively against phosphate buffer (0.05 molar phosphate, pH 6.8 with sodium hydroxide) to remove L-fucose. After clarification in a high speed centrifuge the protein solution was frozen and stored at -70° C. From 100 g of flour, 45 mg of protein was obtained.

Some physical properties of the isolated protein in 0.05 molar phosphate buffer, pH 6.8, are:  $\lambda_{\max}$  282 m $\mu$ ,  $E_{1\%}^{1\text{cm}}$  17.5;  $\lambda_{\min}$  250 m $\mu$ ,  $E_{1\%}^{1\text{cm}}$  6.2. The isolated protein was homogeneous in its sedimentation pattern ( $S_{20}$  6.23, for a concentration of 7.5 mg/ml.). The weight-average molecular weight was found to be 107,000 by the sedimentation equilibrium method assuming a partial specific volume of 0.75.

The isolated protein was found to agglutinate group O human red blood cells (0.1 per cent suspension in 0.85 per cent sodium chloride, 0.02 molar phosphate buffer, pH 6.8, 22 per cent C). The minimal protein concentration for agglutination was 38  $\mu$ g/ml., as determined by the two-fold dilution technique. The agglutinating potency of the purified protein was increased, however, to a minimal agglutinating concentration of 2.4  $\mu$ g/ml. by addition to the test mixture of a diluted crude aqueous extract derived from *L. tetragonolobus* as previously described. The dilution of extract used (1:50) caused no agglutination because the highest dilution for agglutination was 1:12.

Inhibition of haemagglutination by a number of saccharides was determined by the two-fold dilution technique. The test mixture contained 38  $\mu$ g of isolated protein/ml of dilute extract (1:50). The minimal concentrations for inhibition were 20  $\mu$ g/ml. of methyl  $\alpha$ -L-fucopyranoside 40  $\mu$ g/ml. of L-fucose, 5 mg/ml. of D-arabinose, 5 mg/ml of D-ribose, and 20 mg/ml. of D-fucose. These data are in agreement with the findings of Morgan and Watkins concerning the haemagglutination inhibition of *L. tetragonolobus* extract by various saccharides. It is thus sug

Fig. 1. Plot of binding data. Protein concentration, 0.7–2.7 mg/ml. Temperature, 3° C.

gested that the isolated L-fucose binding protein carries the specificity of the haemagglutinating system.

Binding of L-fucose by the isolated protein was determined by the equilibrium dialysis method using L-fucose labelled with carbon-14 (0.41 mc./mmole, Calbiochem, Los Angeles). In each dialysis cell (Technilab Instruments, Los Angeles) one compartment was filled with 1 ml. of protein solution and the other with 1 ml. of buffer solution. The membrane was made of Visking dialysis tubing. Labelled L-fucose solution (0.5–10  $\mu$ l.) was added to the protein or to the buffer. After 20 h of gentle stirring at 3° C, duplicate samples of 100  $\mu$ l. from both compartments of the dialysis cell were transferred to 15 ml. of Bray's solution for determination of counting rates (Packard 'Tri Carb' scintillation counter). At least 50,000 scintillations were counted for each sample. Counting rates of a blank and of a standard solution were determined as well. The concentration of a stock solution of labelled L-fucose was determined by the method of Park and Johnson<sup>4</sup> and the specific counting rate was found to be 4,056 c.p.m./ $\mu$ g. The concentration of protein was measured spectrophotometrically.

The results of binding experiments at concentrations of protein from 0.7 to 2.7 mg/ml. are plotted in Fig. 1 according to the equation (compare Scatchard<sup>5</sup>)

$$r/f = -Kr + NK$$

where  $r$  is the number of moles of L-fucose bound/g of protein,  $f$  is the molar concentration of free L-fucose,  $K$  is the intrinsic binding constant, and  $N$  is the number of moles of binding sites/g of protein. Fig. 1 shows that the experiments were performed in conditions ranging from a low degree of coverage to near saturation of the binding sites. The fact that a straight line fits the experimental point shows that the binding sites are equivalent and independent, and the  $K$  and  $N$  are independent of protein concentration. From the slope we obtain  $K = 1.1 \times 10^4$  l. mole<sup>-1</sup> and from the  $x$ -intercept  $N = 3.6 \times 10^{-5}$  moles of sites/g of protein or 3.9 sites for each protein molecule ( $\bar{M}_w = 107,000$ , see previously).

Stereospecificity of the binding sites was demonstrated by comparing the ability of the enantiomers, L-fucose and D-fucose (Pfanstiehl Laboratories, Inc., Waukegan, Illinois) to inhibit the binding of labelled L-fucose. A hundred-fold excess of D-fucose does not interfere with binding of the label, whereas L-fucose interferes as expected.

We thank Mr I. Jacobson and Mr A. Lustig for technical assistance.

## MICROBIOLOGY

### Lysis of *Escherichia coli* by Marine Micro-organisms

INVESTIGATIONS of the lethal effect of seawater on *Escherichia coli*, the common indicator organism for pollution by intestinal pathogens, have suggested a variety of possible mechanisms<sup>1–3</sup>. The negative effect of heat sterilization of seawater on its specific bactericidal action indicates a biological interaction which has been neither confirmed nor disproved. We attempt to define here the role of the native microflora in the disappearance of *E. coli* from seawater.

We studied the relationship between the size of the marine microbial population and the rate of death of *E. coli* using seawater concentrates of different population densities. Fresh seawater, sampled at Nahant and Woods Hole, Massachusetts, was centrifuged at 4,000*g* at 10° C and the bacterial count of a series of concentrates was determined by surface plating on a peptone-yeast extract agar<sup>4</sup>. 100 ml. quantities of autoclaved seawater to which different concentrations of marine micro-organisms had been added were placed in 250 ml. Erlenmeyer flasks. Strain K12 of *E. coli* was grown in nutrient broth and

Fig. 1. Plot of the log of the number of *Escherichia coli* present in autoclaved seawater after the addition of different concentrations of marine micro-organisms.  $\Delta$ , Autoclaved seawater;  $\circ$ , autoclaved seawater plus ten marine bacteria/ml.;  $\bullet$ , autoclaved seawater plus  $10^3$  marine bacteria/ml.;  $\blacktriangle$ , autoclaved seawater plus  $10^4$  marine bacteria/ml.

was inoculated into all flasks at a concentration of  $10^6$ /ml. The mixture was incubated at  $26^\circ\text{C}$  on a rotary shaker. Viable counts of *E. coli* were made at regular intervals on eosin methylene blue agar at  $37^\circ\text{C}$ .

The results (Fig. 1) show that the decrease in numbers of *E. coli* was strongly affected by the size of the marine microbial population. Almost no decrease was detected in autoclaved water. As the concentration of marine bacteria in the water increased, so also did the rate and extent of death of *E. coli*.

In parallel experiments we investigated the survival of *E. coli* in samples of seawater taken from the Atlantic Ocean 150 miles off Cape Cod, Massachusetts. Populations of *E. coli* added to the water declined from  $10^9$  cells/ml. to  $10^7$  cells/ml. in 5 days when the total marine bacterial population was about  $10^5$  bacteria/ml. By comparison, the population of *E. coli* declined from  $10^9$ /ml. to  $10^4$ /ml. in 5 days in seawater sampled from the harbour at Woods Hole, Massachusetts, which had a bacterial population of about  $10^6$ /ml.

The development of a specific lytic microbial population after inoculation of *E. coli* into seawater was indicated by the results of later experiments, in which *E. coli* was re-inoculated to natural seawater 5 days after the initial inoculum. As shown in Fig. 2, the lag phase of the death curve of *E. coli* was virtually eliminated in the second curve. The number of *E. coli* cells declined from  $10^6$ /ml. to  $10^2$ /ml. in 4 days following the second inoculation, compared with 7 days following the initial inoculation into seawater. The indigenous marine bacterial population remained constant at  $10^4$ /ml. throughout the experiment.

The stimulation of the lethal activity of seawater by the addition of *E. coli* suggested the enrichment of a microflora parasitic or lytic to *E. coli*. In later experiments, *E. coli* was added to natural seawater in Erlenmeyer flasks as before. Samples of the water were taken at daily intervals and placed on double layer plates containing autoclaved seawater and 1.5 per cent agar in the bottom layer. The top layer contained autoclaved seawater with 0.7 per cent agar and inoculated with  $10^{10}$  cells of *E. coli* K12/ml.

Two kinds of responses were recorded after 2–3 days: (1) the appearance of bacterial colonies surrounded by a

Fig. 2. Accelerated decline of the population of *Escherichia coli* in natural seawater with a re-inoculation of *E. coli* after 7 days. ○, First inoculum of *E. coli*; ●, second inoculum of *E. coli*.

Fig. 3. Plaques observed when seawater exposed to *Escherichia coli* was inoculated onto double layer plates of autoclaved seawater and *E. coli*.

clearing zone in the bacterial lawn; (2) the appearance of clearing zones without visible colonies (plaques). Tests showed that the organisms isolated from the colonies were capable of utilizing the cell walls of *E. coli* as a sole source of organic carbon. Lysis was caused by degradation of the cell walls by extracellular enzymes. In a previous report<sup>5</sup> we described the isolation of similar bacteria from seawater and their activity in killing *E. coli* in artificial seawater.

After exposure of seawater to *E. coli* for 5 days, the number of plaques increased from about 10/ml. in natural water to  $10^3$ /ml.—as measured by the double layer technique. In samples from the plaques, phase contrast microscopy revealed the presence of large numbers of highly motile vibrios ranging in size from 0.2 to 0.5  $\mu$ . These bacteria did not grow on the peptone-yeast agar used in this study and seemed to be obligate parasites. They were also halophilic. Plaques regularly appeared in 3 days on *E. coli* K12 or B double layer plates at  $22^\circ\text{C}$ . Very few of these plaques were obtained with natural seawater, unless previously inoculated with *E. coli*. These organisms appear to belong to the genus *Bdellovibrio* as originally described by Stolp and Petzold<sup>6</sup>, and named by Stolp and Starr<sup>7</sup>. Typical newly formed plaques are shown in Fig. 3.

The fact that the lethal effect of seawater on *E. coli* increases (a) with increasing population size, as determined on a peptone-yeast extract agar, and (b) with an increasing number of lytic bacteria on inoculation with *E. coli* supports our assumption that the indigenous microflora contributes significantly to this effect. A more complex effect is suggested by the results of studies on other qualities of seawater, especially heavy concentration of metal and the presence of algal toxins. It seems reasonable to assume that the nature of the lethal effect of seawater on *E. coli* will vary with seasonal and local changes of the environmental conditions.

### 'Viractin'

It has been claimed that 'Viractin', a complex mixture of substances obtained from the mother liquors of *Streptomyces griseus* fermentation, reduced the incidence of influenza and other respiratory diseases when it was allowed to evaporate from a gauze pad suspended in the sleeping compartment of patients in a mental hospital<sup>1</sup>. Investigators are agreed, however, that it has no demonstrable *in vitro* antiviral activity and evaporation into the air does not protect mice against experimental influenza virus infection<sup>2</sup>. It has been pointed out that a negative result in experimental animals does not mean that the material is negative in man<sup>3</sup>. A further trial has therefore been conducted among members of the staff of the Post Office Branch of the Treasury Medical Service.

The 'Viractin' was an authentic sample used in earlier studies and was used in the manner and at the rate prescribed by Leach *et al.*<sup>1</sup>. Volunteer members of the staff were recruited and agreed to place impregnated pads in their bedrooms. Half of them (randomly selected) in each section of the trial received pads containing active material and the other half containing a dummy material (benzaldehyde in 90 per cent ethanol with colouring). Each volunteer received a diary card, similar to that used by Hope-Simpson<sup>4</sup>, on which he recorded the following symptoms: sore throat, cold in the head, headache, feverishness and aches in the back and limbs. For the purpose of assessment of the cards only those symptoms recorded for 2 days consecutively or more were regarded as significant. The volunteers did not know the nature of the substance on the pads and the cards were evaluated twice with closely concordant results by physicians who also did not know what material was being used. The first section of the trial included 39 volunteers who were treated and observed between September 26 and November 20, 1966. In the second half, between January 16 and February 24, 1967, all the subjects treated with 'Viractin' were given control material and vice versa. The results are shown in Table 1.

Table 1

Group	No.	Substance	Period	No. of respiratory infections occurring	No. of persons infected	No. of infections/person/week of observation
A <sub>1</sub>	20	'Viractin'	8 weeks	7	6	0.04
B <sub>1</sub>	19	Placebo	8 weeks	22	9	0.14
A <sub>2</sub>	20	Placebo	8 weeks	5	5	0.04
B <sub>2</sub>	19	'Viractin'	6 weeks	15	8	0.13
A <sub>1</sub> and B <sub>2</sub>	39	'Viractin'	Both	22	14	0.04
A <sub>2</sub> and B <sub>1</sub>	39	Placebo	Both	27	13	0.05

Recording continued for a further period of 8 weeks after the solutions were withdrawn, with the following results:

A <sub>1</sub>	20	8 weeks	3	2	0.02
B <sub>1</sub>	19	8 weeks	8	6	0.05

It can be seen that in the first half of the trial those given 'Viractin' fared slightly better than the controls; in the second half the controls fared better. It was concluded that there was no evidence of an effect on virus infections comparable with that reported by Leach *et al.*

It would appear that the original placebo group (B<sub>1</sub>), although randomly selected, had an increased susceptibility to upper respiratory infection which they carried with them throughout all phases of the trial.

I am grateful to Dr Tyrrell for the 'Viractin', some of the equipment and his advice, and the London Materials Section of the GPO for the control substance.

## PSYCHOLOGY

### Binocular Depth Perception of "Julesz Patterns" viewed as Perfectly Stabilized Retinal Images

THE role of eye movements in the promotion and maintenance of binocular fusion and depth perception is not clear, although experiments<sup>1-3</sup> suggest that judgements of depth in a stereoscopic situation may be made with some accuracy in the absence of eye movements. Langlands found reliable perception of depth in normal vision with short exposures of the order of 10<sup>-5</sup> sec, but it seems uncertain whether judgements could have been influenced by after-images. It should be possible in principle to solve this problem by "stabilizing" images on the retina after the method of Ditchburn<sup>4</sup> and Riggs<sup>5</sup>, and in 1963 one of us (C. R. E.) tried to study binocular vision with a contact lens stabilizing system in each eye, but with inconclusive results. Partial destabilization because of poor contact lens fit was a probable cause of this lack of success, as Barlow pointed out in a general criticism of this method<sup>6</sup>. Experiments with an after-image as a "perfectly stabilized image" have been undertaken here<sup>7</sup>, and, because with suitable methods prolonged clear after-images of patterns can be obtained, we decided to try to study complex stereoscopic patterns in these conditions. (Because the after-image is formed as the result of temporary changes in the state of the retinal cells themselves, it can be considered to be a completely "stabilized" image.)

Fig. 1. Stereo pair. Truncated pyramid viewed from above.

Early experiments used patterns such as those in Fig. 1; more than 100 casual subjects described the effects when patterns 1a and 1b were flashed to left and right eyes. Results were ambiguous, approximately 50 per cent reporting that the fused central square was seen "in depth", the remainder stating that the image appeared two-dimensional. The simplest hypothesis to account for the discrepancy seemed to be that the diagrams employed allowed inferences about "depth" to be made from the special nature of the patterns—which could be likened to a corridor or to a truncated pyramid seen from above. Clearly, patterns in which inferences about depth cannot be obtained must be employed. Accordingly, we considered the well known random-brightness patterns designed by Julesz of Bell Telephone Laboratories

Fig. 2. Julesz stereo pair which gives centre square in front of the background.

Fig. 3. Stereo pair which gives centre square in front of the background. Our modified Julesz patterns.

(Fig. 2) which when viewed in a stereoscope show a central square standing in depth—this in the absence of any perspective or monocular form cues. Retinal disparity alone, arising from a horizontal shift of the central portion of the otherwise identical patterns, is a sufficient cue to depth<sup>6</sup>. The after-image technique of retinal stabilization consists of viewing a bright flash discharged from behind a cut-out or high contrast photographic slide with its black parts very dense. If a Julesz pattern is so viewed, the very large number of component squares or "picture elements" cannot be resolved in the after-image, and thus, of course, there can be no depth perception. This was solved by devising the pair of patterns shown in Fig. 3—which are basically similar to Julesz patterns but with the number of components reduced. The white circles (picture elements) were placed on the intersections of a  $25 \times 25$  rectangular grid, their position being determined by random numbers. The relative shift of a  $10 \times 10$  central portion is one "picture element".

The patterns were photographed on  $2 \times 2$  in. slides and mounted in a lens stereoscope, at a distance from the lenses equal to their focal length. Infra-red absorbing filters and tracing paper to diffuse the light were mounted behind the slides, and a septum was provided. A single photographic flashlight illuminated both slides.

A fixation point in the form of a black dot on a small white square of paper was attached to each slide, the

points lying in corresponding positions on the outer portions of the slides—specifically, in the row of circles directly above the "inner square" of circles. Experiments were conducted in a darkened room, although subjects were not dark-adapted. The front of the slides was dimly illuminated so that on looking into the stereoscope, a subject could see only the fixation points. Subjects were instructed to fixate, and when the markers were fused, to discharge the flash unit for themselves by pressing a button. The 1 msec flash, provided by gas discharge from a Courtenay 'Major Mark 2' power pack, had an output of 1,000 joules—so bright that detail in the slides at the moment of the flash could not be observed. Within 2 sec, however, the "after-image" became clear, and the detail of the picture elements emerged. The characteristic fading and regeneration cycle of the after-image was forestalled<sup>9</sup> by requiring subjects to face, with closed eyes and at a distance of about 6 in., a stroboscope flashing at approximately 5 cycles/sec. In these conditions, all subjects could see the fused patterns in some detail, and for a period of 10–15 sec.

Without knowing the direction of "depth" in advance of a flash, ten subjects were each given a series of twenty pairs of after-images, randomly ordered with ten "square-in-front" and ten "square-in-back" configurations. Subjects were allowed 15 sec to view the after-image, after which, if they had not already made a judgement, they

were invited to "guess". Few such forced choices in fact had to be made. Subjects' confidence in their choices were reported and noted. There was a 5 min interval between flashes, and no knowledge of results was given until the end of the series. Of the ten subjects, seven were correct seventeen or more times out of twenty, while three were not significantly better than chance ( $P < 0.001$  on the binomial test). Of those subjects who could definitely tell the plane of depth in the after-image, none made an error when confident of his judgement.

In a subsidiary experiment, a number of casual subjects were shown Julesz patterns in a normal stereoscope, and all those making a correct judgement of depth were then given a pair of after-images using our modified patterns; 85 per cent of them made correct judgements on this single observation.

It is therefore evident that stereoscopic depth perception of complex displays can be attained in a perfectly stabilized image, that is in the absence of eye movements, both voluntary and involuntary. Subjective impressions of the strength of the depth effect varied from subject to subject, but to some it appeared striking. The central square was frequently seen to "build up" from its surround. The occasional errors recorded by even the most reliable subjects can probably be attributed to imperfect fixation before the flash, resulting in slight non-correspondence of the stereo pairs.

## Stimulus Probability and Simple Reaction Time

SIMPLE reaction time tasks usually contain procedures designed to reduce or eliminate the frequency with which subjects anticipate the onset of the stimulus. These measures include varying the interval or foreperiod between the warning stimulus and the subsequent stimulus, and introducing a number of "catch trials" on which the stimulus does not follow the warning. Obviously, one effect of including catch trials is to lower the overall probability that the stimulus will follow the warning stimulus. In view of the known importance of stimulus probability in choice reaction time situations, it is perhaps surprising that, although there have been several studies (for example, refs. 3-5) of the effects of changes in the range and variability of foreperiods, there appears to have been only a single study in which the effect of changing the frequency of catch trials has received systematic investigation. Drazin<sup>3</sup> introduced catch trials to produce three levels of probability of occurrence of the stimulus ( $s$ ):  $P(s) = 1.0$ ,  $0.9$  and  $0.5$ . These levels were allowed to interact with mean foreperiod, so that Drazin's results regarding the effects of  $P(s)$  on reaction time are limited to the demonstration of (1) an inverse relationship between  $P(s)$  and reaction time, and (2) an interaction between  $P(s)$  and the reaction time-foreperiod relationship. The study reported here was designed to examine the relationship of the  $P(s)$  and

reaction time over a wide range of  $P(s)$  values in a sequential, simple reaction time situation.

A metronome-uniselector unit produced a regular series of warning stimuli, each consisting of a brief flash from a 12 V bulb placed at eye-level 1 m in front of the seated subject. Average response rate was held constant by adjusting the rate of presentation of warning stimuli inversely to  $P(s)$ —a procedure which also equates the length of time required to record the same number of reaction times at different values of  $P(s)$ . Mounted below the warning light was a 12 V relay, the arm of which produced a clearly audible click when the relay was energized. The subject responded to this click by closing a microswitch with the thumb of the preferred hand. The construction of the uniselector was such that the overall probability of the stimulus following a warning stimulus could be varied from 0.1 to 0.9 in 0.1 steps. In all conditions of the experiment blanks were randomly positioned in the stimulus sequences. By holding constant the interval between each warning stimulus and the subsequent stimulus (if one had been selected) at 750 msec in all conditions, the uncertainty of the subject as to when the stimulus would occur was reduced as far as possible: the remaining uncertainty was thereby restricted to that associated with the occurrence/non-occurrence of the stimulus. The rate of presentation of the sequence of warning stimuli varied from 1/1.5 sec in the  $P(s) = 0.1$  condition, to 1/13.5 sec in the  $P(s) = 0.9$  condition; the average interval between successive stimuli (and successive responses) was thus 15 sec in all nine experimental conditions.

Condition mean		268	216	208	193	170	174	163	168	163

Six male psychology students, all with some experience of reaction time experiments, acted as subjects and were individually tested. All subjects were informed of the  $P(s)$  value appropriate to each experimental condition and were given a short practice period with immediate knowledge of results before each test session. Test sessions lasted for about 12 min each and all subjects were tested under all conditions in a different random order. Subjects were tested under five conditions on the first and four conditions on the second of two consecutive days. A 4 min rest period was allowed between successive test sessions. Fifty reaction times (measured to the nearest msec) were recorded during each test session.

Results obtained are summarized in Table 1. Errors were also recorded but, probably as a result of the instructions given to subjects, were too rare to allow sufficiently detailed analysis: in 2,700 stimulus presentations there was a total of only twenty-nine failures to respond, and only eleven responses which anticipated the onset of the stimulus.

The mean reaction times of the subjects were subjected to a two-way analysis of variance which revealed significant differences between subjects,  $F(5, 40) = 9.8$ ,

Fig. 1. Simple reaction time as a function of stimulus probability.  
Reaction time =  $154 P(s)^{-0.25}$ .

$P < 0.001$ ; and between the nine experimental conditions,  $F(8, 40) = 29.5$ ,  $P < 0.001$ . The eta-square test was applied to the nine condition means: this yielded  $\eta^2 = 0.726$ ,  $\chi^2 = 15.4$ ,  $P < 0.05$ , indicating that the relationship between mean reaction time and stimulus probability departs significantly from linearity.

A series of curves was fitted to the nine condition means of Table 1, the sum of the squared differences ( $\Sigma d^2$ )

between actual and predicted values forming an index of the goodness of fit of each function. Linear, quadratic and cubic polynomial functions gave  $\Sigma d^2$  values of 2,123, 457 and 313 respectively. A function of the form  $Y = aX^b$  was then fitted, giving  $\Sigma d^2 = 318$ , and it is this curve which is shown in Fig. 1.

The increase in reaction time as a function of decreased stimulus probability occurs as a general shift of the reaction time distribution rather than by the addition of a few very long reaction times: reference to the medians recorded in Table 1 and examination of plots of individual times support this conclusion. Illustrative data are shown in Fig. 2 where reaction time distributions from the fastest and slowest subjects (overall) are plotted as histograms.

These results indicate that the use of catch trials in simple reaction time situations may do more than prevent complete anticipation; it may effect mean latency by shifting the distribution of reaction times. The largest change in mean reaction time occurs at the extreme of the probability range (that is, between the  $P(s) = 0.1$  and  $P(s) = 0.2$  conditions); across other conditions the changes in mean reaction time are fairly small. It follows that in most simple reaction time situations, the customary frequency of catch trials will change  $P(s)$  values over a range where their effects are minimal; however, if catch trials are introduced, together with varied foreperiods and a constant warning stimulus rate, the various sources of slowing may summate or act multiplicatively.

The fact that the mean reaction times of the subjects tend to vary as a function of stimulus probability reinforces the view<sup>1</sup> that the reaction time task may be considered as a pay-off situation. If this view is correct then, even though the present results indicate that catch trial effects are likely to be relatively small, it would seem important in any theoretical analysis of a simple reaction time situation to consider not only the rewards and penalties associated with the behaviour of the subjects, but also the probability of occurrence of those events to which he is set to respond.

I thank Dr J. Szafran and Dr A. Staniland for advice. This work was supported by a SRC research studentship.

### Relationship between Circadian Rhythm of Body Temperature and Introversion-Extraversion

It has frequently been alleged that people can be divided into "morning" or "evening" types (see, for example, ref. 1). Supporting evidence for this view has been obtained by Colquhoun<sup>2</sup> and Colquhoun and Corcoran<sup>3</sup>, who found that the sign of the correlation of a personality measure—degree of introversion—and performance efficiency was dependent on the time of day at which testing was done. At two visual inspection tasks, introverted subjects performed better than extraverts in the early morning; the position was reversed in afternoon tests. The aim of the investigation reported here was to determine whether these differences were associated with underlying differences in circadian physiological rhythm as indicated by body temperature.

Using standard clinical thermometers the sub-lingual body temperatures of seventy-four young men were recorded twenty times during a single 24 h period, on two occasions separated by approximately 1 week. Read-

Table 1. CORRELATION COEFFICIENTS ( $r$ ) OF BODY TEMPERATURE AND INTROVERSION RATING AT TWENTY TIMES OF DAY ( $N=74$ )

Time	0500	0700	0800	0900	1000	1100	1200	1300	1400	1500	1600

Time	1700	1800	1900	2000	2100	2200	2300	0100	0300		
$r$	-0.042	0.060	-0.016	-0.114	-0.239†	-0.167	-0.229‡	-0.207‡	-0.025		

\*  $P$  (one-tailed)  $< 0.001$ ; †  $P$  (one-tailed)  $< 0.025$ ; ‡  $P$  (one-tailed)  $< 0.05$ .

ings were taken hourly between 0700 and 2300 h, and two-hourly between 2300 and 0700 h during the sleep period of the subject. From 0800 to 1630 h the men were intermittently employed on light duties (mainly short psychological tests); meals were taken at 0700, 1200 and 1700 h. The evening was devoted to light indoor recreation. All subjects were given the Heron Personality Inventory<sup>4</sup> to determine their placing on the personality dimension of introversion-extraversion as measured by their score on the "unsociability" scale. Body temperature at each of the twenty times of day was taken as the mean of the two readings obtained. Although the grand average of these twenty means was not significantly correlated with introversion-extraversion ( $r = -0.044$ ), some significant correlations were observed when individual times of day were considered separately (see Table 1).

Not only the magnitude of the correlation but also its sign appeared to vary in a systematic manner depending on the time of day. Thus the correlation changed from significantly positive (introverts with higher temperatures) to significantly negative over the period from 0800 to 2100 h, that is, over the "active" part of the waking day. During sleep this trend was reversed.

Thirty-nine of the subjects had a score of three or less on the Heron Inventory; the remaining thirty-five subjects had a score of 4 or more (a high score indicates a relatively high degree of introversion). Average tempera-

tures for these two groups were computed separately at each time of day. Two-point rolling means of the resulting values are shown in Fig. 1.

The curve of body temperature through the 24 h period was, in both groups, characterized by a division into three distinct phases: (i) a rapid rise between 0500 and 1000 h; (ii) a further, considerably slower rise between 1000 and about 2000 h; (iii) a rapid fall between about 2000 and 0500 h. Thus the curve is not, as is sometimes suggested, a simple sinusoid.

There was no significant difference in the mean maximal range of temperatures recorded from the two personality groups ( $t=0.178$ ,  $P=0.22$ ); the peak-trough change was about  $1.2^{\circ}\text{F}$  in both groups. Inspection of the curves in Fig. 1 suggests that the temperature of the more introverted subjects rose more rapidly in the early morning and (possibly) started to fall at an earlier point in the late evening. This is brought out more clearly in Fig. 2, in which average temperatures are shown for only those subjects having Heron Inventory scores of either 2 or less (twenty-two cases) or 5 or more (twenty-five cases); again, there was no significant difference in mean temperature range for these more extreme personality groups ( $t=0.186$ ,  $P=0.21$ ). Analysis of variance of the temperatures of the extreme groups revealed a statistically significant interaction between Inventory score and time of day ( $F_{19,555}=1.85$ ,  $P<0.025$ ). It can therefore be concluded that the differences in the circadian rhythms shown in Fig. 2 are reliable.

Although relatively small, this relationship between personality, body temperature and time of day may help to explain the performance differences in introverts and extraverts referred to previously, if it is assumed that temperature reflects the level of "arousal" of the nervous system, and that performance efficiency is related to this level. Comparative measurements with a variety of different groups would be necessary to determine whether the relationship (and also the form of the body temperature curve observed) is characteristic of the particular type of subject used, or whether it is typical of the population at large.

## GENERAL

### Analysis and Design of Certain Scaling Experiments

IN certain psychological scaling techniques, direct pair comparison judgments of the differences between, or ratios of, magnitudes of attributes of objects (for example, volume or pitch of tones, heaviness of weights, painfulness of electric shocks) are elicited from a single subject<sup>1</sup>. We have investigated the statistical analysis of data thus obtained and the problem of optimal experimental design.

Fig. 1. Mean circadian rhythm of body temperature in introvert and extravert groups.

Fig. 2. Mean circadian rhythm of body temperature in relatively extreme introvert and extravert groups.

There are two cases to be considered: (1) the complete case, where all  $\binom{n}{2}$  possible pairs of the  $n$  objects are presented once each to the subject for judgment; (2) the incomplete case, where fewer are presented.

In the complete case it is well known<sup>2</sup> that if each judged difference is treated as consisting of a true difference between magnitudes, and error,  $d_{ij} = x_j - x_i + e_{ij}$ , then convenient least squares (L.S.) estimates of

the magnitudes are given by  $x_i = \frac{1}{n} \sum_j d_{ij}$ , and that ratio

judgments can be treated similarly by first taking their logarithms, and then taking antilogarithms of the average (because such a reduction is always possible with ratio judgments, they will not be mentioned separately any

more). The estimates have variance  $\frac{(n-1)}{n^2} \sigma^2$  and

covariance  $\frac{(-1)}{n^2} \sigma^2$ , where  $\sigma^2$  is the variance of the  $e_{ij}$ .

We suggest the following further analysis of data. The total raw sum of squares of judged differences,  $\sum_{i < j} d_{ij}^2$ ,

with  $\binom{n}{2}$  degrees of freedom (d.f.), is composed of two orthogonal sums of squares (S.S.), due to differences between estimates,  $\sum_{i < j} (\hat{x}_j - \hat{x}_i)^2$ , with  $(n-1)$  d.f., and error,

$\sum_{i < j} e_{ij}^2$ , with  $\binom{n-1}{2}$  d.f. It seems advisable to investigate

systematic distortion in the judgments by extracting from the error S.S. Tukey's S.S. for non-additivity<sup>3</sup>. Then an analysis of variance can be carried out which tests independently both the null hypothesis that  $x_1 = x_2 = \dots = x_n$ , and also that the judged differences are of the form supposed. In certain cases the analysis can be refined by dividing the estimates S.S. into a component attributable to some effect of psychological interest, for example, the psychophysical power law<sup>4</sup>, and an orthogonal remainder.

With more than about fifteen objects the number of judgments required of the subject in the complete case rapidly becomes unmanageable, which leads us to consider the incomplete case. Kaiser has suggested a convenient form of the L.S. estimation equations (personal communication):  $\hat{\mathbf{X}} = \mathbf{K}^{-1} \mathbf{\Sigma}$ , where  $\hat{\mathbf{X}}^{n \times 1}$  is a vector of estimates,  $\mathbf{\Sigma}^{n \times 1}$  is a vector of sums of judgments associated with the row object, and  $\mathbf{K}^{n \times n}$  a matrix of which the diagonal elements are equal to the number of objects with which the relevant object has been compared +1, and the off-diagonal elements are 0 or 1 according to whether the row object has or has not been compared with the column object. It is easily shown that the variance-

covariance matrix of the estimates is  $\sigma^2 \left[ \mathbf{K}^{-1} - \frac{1}{n^2} \mathbf{U} \right]$ ,

where  $\mathbf{U}^{n \times n}$  is the matrix with each element 1.

With appropriate changes in the d.f., the same analysis of variance may be used as in the complete case.

Two principles appear relevant to the selection of experimental designs in the incomplete case: first, each object should be treated in exactly the same way; second, the design should give as accurate estimates as possible.

To formalize the first principle, it is convenient to represent a design as a graph<sup>5</sup>, in which the vertices stand for objects, an edge connecting two vertices indicates that the corresponding objects are compared, and the absence of an edge that they are not. A graph is defined to be transitive if, for any ordered pair of vertices, there is an operation in its group of automorphisms which takes the first into the second, that is, if the group, considered as a permutation group on the vertices, is transitive<sup>6</sup>. This implies that the graph is regular, that is, that each vertex has the same number, say  $k$  (which must be even if  $n$  is odd), of edges, but the converse does not hold.

Fig. 1.

For example, in Fig. 1 graph (a) is regular but not transitive (because no vertex will go into another with a different letter), while graphs (b) and (c) are transitive. The first principle is then realized by considering only transitive graphs.

As regards the second principle, a graph gives as good as or better estimates of all linear functions of the object values if, and only if, the difference between their estimation variance-covariance matrices is positive semi-definite. Unfortunately this requirement fails to discriminate very well between different transitive graphs, so instead we use the less stringent condition that the optimal graph shall have a smaller estimation variance for the object values than any other, that is, that the diagonal elements of  $\mathbf{K}^{-1}$  shall be as small as possible.

We have not found any simple method of determining such optimal graphs, and are therefore carrying out a systematic computer-assisted search (which is expected to take quite some time) through all transitive graphs for which  $n \leq 25$  and  $\frac{nk}{2} \leq 100$ , to find those with smallest diagonal elements in  $\mathbf{K}^{-1}$ .

The experimental procedure here is essentially the same as that in Stevens's<sup>7</sup> method of magnitude estimation, in which the subject is presented with a reference object, which is assigned some standard numerical value, and then asked to estimate the magnitude of each of a set of test objects, which are presented one at a time but several times each, because these magnitude estimates are clearly implicit ratio judgments. The design has the following advantages and disadvantages over those discussed here.

(1) In Stevens's design the reference object tends to exert a slight distorting effect on the estimates obtained, which should not occur here, because there is no constant reference object.

(2) Stevens's design makes it impossible to test for distortion in the judgments by means of Tukey's S.S. for non-additivity.

(3) Stevens's design has the advantage that the estimates are not correlated, while in those discussed here they are. (The correlation in general varies from one pair of objects to another, but its average for any transitive graph is  $-1/(n-1)$ .)

(4) The variance of the estimates for an optimal transitive graph over the range of  $n$  and  $k$  we have considered appears to be very roughly half that with Stevens's design and the same number of objects and judgments.

## INTERPLAY AMONG PRIMATES

### Social Communication among Primates

Edited by Stuart A. Altmann. Pp. xiv + 392. (Chicago and London: The University of Chicago Press, 1967.) \$15; 105s. net.

RECENT literature on primate behaviour has not included a book entirely on communication. This volume is based on the 1964 Montreal symposium, "Communication and Social Interaction in Primates", but while the title of the book has become more specific than this, the subject matter has not. Thus the sections are headed "Reproductive Behaviour", "Agonistic Behaviour", "Causal Mechanisms", "Social Dynamics" and "Communication Processes". There is, however, a well-hidden clue to this apparent discrepancy in the seventeenth chapter, "The Structure of Primate Social Communication", in which Altmann discusses the definition of communication. His solution that "social communication is a process by which the behaviour of an individual affects the behaviour of others" makes the concept a very broad one and enables him to include as communication "the influence of a wrestler on the behaviour of another, of a ballet teacher as she re-positions the body of a student . . .". If one accepts this there is no difficulty about reproductive and agonistic behaviour being communication, and indeed all actions of one animal towards another. It is more usual, however, to confine the concept to those systems where a stimulus is transmitted through the environment, and where the reception of this "signal" is advantageous to all participants, so that selection will increase the efficiency of the system by acting both on sender and recipients. In this narrower sense only a small proportion of the book is devoted to communication, although much of what is described concerns it. Unfortunately, the summarizing discussions at the ends of the sections are not helpful in putting the individual chapters into a cohesive framework.

The first two chapters concern mating behaviour. That by Jolly on the breeding synchrony of a *Lemuratta* troop presents an excellent, clearly written, quantitative assessment of changes in intra-troop relationships before and after the mating period. Social communication is cautiously suggested as the cause of synchrony, but the dangers of interpretation are emphasized in the following chapter on reproductive cycles, mainly of caged and wild baboons. In this chapter Rowell gives a salutary warning against assuming that a particular change in an animal (in this case the appearance of sexual swellings) is a signal because the behaviour of an interacting animal changes concurrently. The chapter contains another, apparently unintentional, warning about the dangers of interpretation: Rowell argues that because the caged male baboons mounted less at the end of the females' sexually swollen periods than in the middle, they were responding to some other aspect of the stimulus situation. Without, however, information about behaviour of the males when more than one female was swollen simultaneously, it is not clear whether the effect was merely one of changing responsiveness to repeated exposure to a stimulus. Further, Rowell's data clearly show for wild baboons a greater percentage of presentings responded to by mounting when the female is at least partly swollen than when not swollen, while the percentage responded to by intention mountings shows the reverse. Inexplicably, swellings are concluded to make no difference to the male's response; perhaps using the interpretative term "intention mounting" has wrongly led the author into

putting these two responses into one category. Thus although Rowell's contention may well be right, the point seems to remain unproven.

Rosenblum and I. C. Kaufman describe the early mother-infant relations of captive group-living pigtail (*Macaca nemestrina*) and bonnet (*M. radiata*) macaques. The data on changes with age of infant in the amount of, and responsibility for, mother-infant contact is interesting but restricted without further information, including interactions with other group members. Species differences are considered but there is no statistical treatment of the data.

Jensen, Bobbitt and Gordon look more closely at the mother-infant relationship in the pigtail macaque. The infants lived alone with their mothers in either a "privation" or "rich" environment (both highly deprived, judging by the illustrations). The authors attempt the important but difficult task of assessing the roles of mothers and infants in their increasing independence of each other. They omit to say, however, how "interactive locomotion" was distinguished from any other, or that because almost all locomotion must have changed the distance apart of the two animals some differences between them may have been simply a measure of their relative activity.

There are three chapters from the section dealing with agonistic behaviour, two chapters from "Social Dynamics" and one from "Communication Processes" which concern aggressive interactions either between individuals of the same social group, or between conspecific groups.

Kummer discusses interactions in *Hamadryas* baboons involving three animals simultaneously, each with a separate role. His interest lies in the development of tripartite relations of adults (male protects female from another group member) from those of infants (mother defends infant against another group member). He suggests that the one-male groups arise ontogenetically by mother-infant relationships becoming male-infant relationships, and that a male is at first maternal toward the female infants who later form his group. While it seems rash at this stage and in such a context to use labels like "maternal" which have motivational implications, this is a thoughtful and thought-provoking chapter.

J. H. Kaufmann's chapter on the social relations of adult males in a free-ranging band of rhesus monkeys contains a wealth of quantitative data. He states that the males constituted a clear hierarchy expressed through spatial displacements and the exchange of aggressive and submissive signals, yet later says "displacements were highly reliable indicators of rank" and that whereas the amount of aggressive behaviour is not a good indicator of rank "the proportion of aggressive acts to submissive ones is more obviously correlated with rank". His criterion seems therefore to be self-correlated. The importance of defining the criterion used for ranking individuals is rightly emphasized by Sade. His clearly presented chapter, also on rhesus monkeys, describes the gestures of attack and flight, shows the linear nature of the relationships, and discusses the importance of a mother's rank in determining her offspring's rank. Both these chapters are of great interest to anyone concerned with the organization of primate groups.

The late K. R. L. Hall (to whom this book is dedicated) has briefly described the behaviour of wild and captive Patas monkeys (*Erythrocebus patas*). Unfortunately, it is difficult to come to grips with this chapter because the inclusion of raw notes on interactions contrasts uncomfortably with the rather general discussion. Nevertheless the author's great enthusiasm and thoughtfulness are apparent throughout and make the chapter well worth reading.

The section on social dynamics also contains an excellent descriptive, and no doubt difficult, field study of the Aye-Aye (*Daubentonia madagascariensis*). The Petters are to be congratulated. Tsumori's interesting chapter

on Japanese macaques, including observations on newly acquired behaviour, completes the section.

The chapters in the section on causal mechanisms stand apart and indicate the sorts of investigation that can follow studies such as those already outlined. Miller discusses the use of instrumental conditioning as a simple language between the experimenter and the animal in a clear and self-critical chapter. Briefly, one of a pair of rhesus monkeys could see the stimulus but not respond, and the other, being able to see its partner but not the stimulus, could only respond. The results were indicative of communication from the former to the latter.

The chapter by Robinson is largely concerned with the quite different technique of tele-stimulation. Data are given on the production of vocalizations in rhesus monkeys, analysed in relation to brain structure. Surprisingly, although Robinson states that the sounds can be categorized into "several recognizable types" this does not seem to have been taken into account in the analysis. Perhaps the author would have found more order in his results if he had looked more closely at the behaviour of the animals than appears to have been the case.

The long and interesting chapter by Ploog is an important contribution to the literature on squirrel monkeys (*Saimiri sciureus*). It includes an attempt to relate specific brain areas to elements of social behaviour, but mostly consists of an extensive study of the genital display and a careful description of vocalizations which seem to belong elsewhere than in a section on causal mechanisms.

Finally, there are the chapters which really are about communication. Struhsaker gives an extensive catalogue of the noises of vervet monkeys (*Cercopithecus aethiops*) which is made especially valuable by careful observations of the situations in which the noises occurred in the wild. Whereas, however, coughing and sneezing are of social significance in other species, and so it may be worth saying they don't seem to be in this one, I have doubts about including vomiting in the catalogue. Indeed, in view of Altmann's statement in the next chapter that "a communicative act is specialized to the extent that its direct energetic consequences are biologically irrelevant to anything but communication", all three should surely be excluded.

Among a good deal that is puzzling in Altmann's chapter is his continued discussion of analogical versus digital systems when he has already concluded that this is a false antithesis. He continually strives to classify events, but taxonomy should be a tool and not an end in itself. It is not clear that the construction of the category "metacommunication" for messages that convey information about other messages is justified, particularly when the use of multimodal signals is well recognized. The theoretical discussion of communication is important but in this instance communication itself seems in danger of breaking down.

As a collection of papers on primates this book contains a great deal of very valuable quantitative data, and covers a wide range both of species (although omitting the apes) and of important topics. It deserves to be widely read.

YVETTE SPENCER-BOOTH

## VISUAL WORLD AND RETINAL IMAGE

### The Nature of Perceptual Adaptation

By Irvin Rock. Pp. x+289. (New York and London: Basic Books, Inc., 1966.) 45s.

PERCEPTUAL adaptation in its simpler forms—adaptation to changes in brightness or loudness of stimuli, for example—has long been familiar, and its physiological basis is beginning to be understood. The phenomenon turns up, however, in a remarkably wide range of more subtle forms, for which at present only the vaguest of speculative

explanations are available in terms of physiology. By the same token, their study may be expected in due course to supply important clues about the mechanisms of information processing that subserve higher perceptual functions. Dr Rock's book is therefore a timely contribution to a discussion which is increasingly bringing psychologists and neurophysiologists into close and fruitful collaboration.

The book is almost entirely concerned with visual perception: with the changes that take place in the appearance of the visual world as a result of a variety of distortions or transformations of the optical image. These range from the drastic inversion of the whole field by means of prisms or mirrors, to the familiar displacements of the retinal image produced by movement of the head or eyes. In each case, it is possible for the appearance of the world to change radically without any corresponding change in the retinal image, so the physical changes responsible are assumed to take place within the visual nervous system. They may on the one hand entail modifications of structure of a "plastic" type, which persist for a time after exposure and give rise to perceptible distorting after-effects; or they may reflect only the presence or absence of concomitant signals from some other part of the nervous system, which need leave no after-effect.

The great merit of Dr Rock's work lies in his clear-headed distinction between perception studied as a form of experience, and sensory-motor co-ordination studied as an aspect of behaviour. He is quite explicit in taking the first as his main concern. "The problems in perception are concerned with how things look . . . Whatever the difficulties . . . we must face the fact that this is nevertheless the subject-matter we wish to explain . . . For example, in adaptation to prismatic displacement of the image, the fundamental question, I should think, is where do objects appear to be located. Yet many workers in this field prefer to speak of the disruption of sensory-motor co-ordination by prisms . . . While it is true that proper co-ordination is often a sign of correct perceptual localization it is by no means necessarily the case" (page viii). Again: "One of the ever-present dangers in contemporary psychology is the tendency to avoid dealing with its unique problems on their own terms, either by hiding behind the skirts of a hardheaded philosophy of science or by prematurely borrowing the paraphernalia of the natural sciences. No explanation of the changes that occur in prism adaptation is going to be satisfactory if it fails to address itself to the question of why things look different following exposure to prisms . . ." (page ix).

I have given these quotations at length to indicate why this book may be rewarding reading for many outside its professional field. It will certainly invite criticism from those to whom talk of subjective experience is either behaviourally defined or (dogmatically) "meaningless"; and in its choice of phrase here and there (for example, "this essentially private world" on page viii, it may be philosophically vulnerable. But its robust insistence on facing psychological problems as such is to be welcomed as yet another sign of health in a field where extreme positions have too long held sway.

Perhaps the main technical theme of the book is that so long as an optical transformation leaves intact "the relationships of components of the image to one another and to the self as object in the field" (page 268), we ought to find it more surprising that the world appears distorted by that transformation than if it appeared normal, for "the essential information conveyed by the retinal image would seem to remain intact". The fact that the optical image is inverted by the lens of the eye, for example, is irrelevant to our ability to see the world "right way up". Rock then suggests that distortions of perception arise because "memories of the specific character of the normal retinal image . . . influence what is now seen". Here the

terminology seems unfortunate, for what is apparently meant is not an intellectual remembering and conscious making of allowances, but rather some kind of automatic and pre-conscious process of association (page 269): "specific visual memory traces (join) with the stimulus to form the underlying correlate" (that is, of visual perception). Although in certain cases (for example, the discussion of adaptation to a displaced image in the fourth chapter) this blows fresh air through a stuffy area of controversy, it has dangers as a general formula. Clearly, unless an optical transformation makes a difference to perception, the subject must be blind to the corresponding distinction. It may not matter which direction of the retinal image becomes labelled as "up"; but if the perception of "upside-down" is to be possible it is surely to be expected by any theory that an inversion of the image should at first make the world look upside down. Moreover, it is far from clear, as seems to be suggested on page 39, that only "memory traces", and not genetically determined connexions, prevent perception from being indifferent to the orientation of the entire image. The evidence from the behaviour of new-born kittens fitted with inverting prisms, cited on page 53, is at least ambivalent on this point. Conversely, it should perhaps not be taken for granted, as it seems to be on page 11 and elsewhere, that all adaptation must be followed by a corresponding negative after-effect, in terms of which it can be measured.

The value of Dr Rock's book does not hang on the resolution of such points as these. The comprehensive survey it offers of a relatively new and active field would alone earn it a welcome; and for the student in particular it has additional merit as an example of careful, painstaking analysis and integration of evidence in an area abounding in logical and philosophical pitfalls.

D. M. MACKEY

## BIOLOGICAL MACROMOLECULES

### Molecular Architecture in Cell Physiology

Edited by Teru Hayashi and A. G. Szent-Györgyi. (A Symposium held under the Auspices of the Society of General Physiologists, Sept. 8-11, 1964, Woods Hole, Mass.) Pp. viii+252. (Englewood Cliffs, N.J., and London: Prentice-Hall, 1966.) 60s.

THE editors of this symposium volume describe its aim as "an attempt to present the thinking and information available at several levels in the organized state of matter of importance to biologists". The eleven contributions vary very widely in meeting this aim. Interesting and stimulating as these papers may have appeared when presented at the symposium itself, in print they make a rather uneven collection without the coherence that might have been imposed by more ruthless editing. The defects of published symposium proceedings have recently been spelt out in *Nature* (214, 46; 1967) and this volume has its share. Above all it is late; more than two years have elapsed between conference and publication. The result is that some of the papers are quite out of date (notably that by Cantoni on sRNA) while in other fields (such as the structure of antibodies on which Edelman writes) there has been such progress that the paper, while still interesting, would now serve mainly as a report on the way.

The article by Caspar on the design of organized biological structures is a valuable statement of principles and is general enough to stand the passage of years. The price paid in this case for avoiding detailed discussion is an abstractness of presentation which might make rather difficult reading for those not already familiar with the subject, but concrete examples are to be found in the articles by Cohen on fibrous proteins and Van Holde on haemocyanin. Katchalsky gives a most illuminating dis-

cussion of the analysis of the thermodynamics of structural transitions in two systems studied by his school—collagen fibres and polynucleotide helices in solution. These examples could very well serve as useful models in discussing the dynamics of more complicated macromolecular systems.

The articles singled out above deal with molecular architecture at the level which would be of most use to a cell physiologist seeking background knowledge. The short paper by Bright Wilson, while strictly in the field of molecular architecture, deals mostly with the topic of hindered rotation about single chemical bonds and would seem very far removed from the concerns of cell physiologists. It does, however, end on a salutary note of warning that the rules gained from the study of small molecules, though useful and indispensable in the field of complex biochemical molecules, should always be applied with caution. This paper provides a nice contrast with the succeeding article by Scheraga on the principles of protein structure in which he seeks to formulate simple models for polypeptide chains and then more complicated ones for polypeptide chains with different side groups that interact with each other, as in a globular protein. The paper provides a useful guide to the large body of developing literature on the attempts to make quantitative estimates of the forces holding a protein molecule together. It also proves to be an illustration of the difficulty of the theoretical problem and perhaps also shows how far there is to go before the most probable conformation of a protein molecule in solution can be predicted.

Three further articles show a very wide variation in the level and range of this symposium. The paper by Shapiro on the elucidation of the base sequence in DNA seems out of place except in so far as it does show how unfeasible the task is at present. There is an interesting article by McElroy and Seliger on the colours of bioluminescence which describes the role of the enzyme and substrate structure, and while this article perhaps goes the furthest in the symposium towards describing the relation between function and the underlying chemical processes, little is known about the structure of biological macromolecules involved. Finally, there is a paper by Inoué and Sato, which is a more or less complete report of an optical analysis of the distribution and orientation of DNA in cricket sperm, and again, while most interesting, would seem more suitable as an ordinary scientific paper than as a part of the printed proceedings of a symposium.

A. KLUG

## PHOTOSYNTHETIC MECHANISMS

### Biochemistry of Chloroplasts

Edited by T. H. Goodwin. (Proceedings of a NATO Study Institute held at Aberystwyth, August 1965.) Vol. 1: Pp. xv+476. 115s. Vol. 2: Pp. xviii+776. 160s. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press Inc., 1967.)

THESE two volumes contain by far the most complete description so far of the biochemical aspects of the chloroplasts. Some eighty-seven papers are included in this record of the formal proceedings of a NATO Study Institute held at Aberystwyth in 1965. Although the first volume is primarily concerned with structure and chemical composition and the second volume with biosynthesis, there is much overlap. Anyone who needs one volume is likely to require both.

In his introduction, the editor hopes that these volumes "will serve as a basic text for some years for recruits into the field of chloroplast biochemistry". Certainly these proceedings will be most useful to both recruits and veterans, but there are some limitations inherent in this type of collection of individual papers from a meeting. Early obsolescence is one problem, particularly when the

work is in a very active field and appears two years after the oral presentation. For example, achievement of complete photosynthesis (assimilation of carbon dioxide with light energy only) by isolated chloroplasts and at rates comparable to *in vivo* photosynthesis has taken place since the Aberystwyth meeting. Thus the discussions in the first part of the second volume of carbon dioxide assimilation rates which were between 1 and 10 per cent of *in vivo* rates are somewhat dated. Another problem is that the writing is uneven, and the degrees of factuality versus speculation are extremely varied. This variation may be desirable at a meeting, where a principal objective is to stimulate discussion and criticism. Unfortunately, the reader who doesn't attend cannot be a party to these discussions, most of which were apparently carried on in private. The number and length of printed discussions at the end of papers in these books are sparse indeed; there is no discussion at the end of most papers.

The first and second parts of the first volume, on the structure of chloroplasts and chloroplast membranes, contain some excellent electron micrographs, together with interpretations and highly speculative models of the structure down to the level of individual models. There are important differences among the models of chloroplast structure given by Drs Muhlenthaler, Menke, Weier and Benson, and others. Of particular interest are the role and composition of the sub-unit particles seen by all investigators by freeze-etching and staining techniques, and the nature of the binding of sub-units into sheets. A reasonably extended discussion of these interpretations would have been in order. Much useful factual information about the chemical composition of the chloroplasts, lipids, proteins, lipoproteins, nucleic acids and pigments is provided in the balance of the first volume.

The section on nucleic acids, together with the biosynthesis of proteins and nucleic acids from the second volume, provides a most interesting picture of the "autonomy" of chloroplasts within the green cell. One aspect of this is nicely illustrated by a short paper by Dr Gibor. Cells of *Acetabularia* from which the nuclei were removed were grown on  $^{14}\text{CO}_2$ . Subsequent analysis showed that these nuclei-free cells had synthesized DNA labelled with carbon-14.

Dr Wildman provides an extensive discussion of the organization of grana-containing chloroplasts with respect to systems involved in photosynthesis, protein synthesis and RNA synthesis. His proposal that mitochondria-like particles that separate from protuberances of "mobile phase" of the chloroplasts by segmentation are actually mitochondria which have previously fused with the chloroplast should have aroused some discussion, but none is reported.

Other parts of the second volume deal with biosyntheses of carbohydrates, lipids and pigments. These sections contain many excellent factual articles, such as those on lipid metabolism by Bloch and his colleagues, on fatty acids in higher plants by Stumpf, and on the heme and chlorophyll biosynthetic chain by Granick. The fourth part is long and ostensibly concerns photosynthetic phosphorylation, but is actually something of a catchall for electron transport, photophosphorylation, and other aspects of photosynthesis. Much of this is to be found in the proceedings of other photosynthesis meetings.

The second volume returns to structure in the final chapter with a discussion of the relation of biosynthetic mechanism to morphogenesis. As Bogorad points out, although the sequence of structural changes occurring during the development of plastids is well established, the order of biochemical events is still very uncertain. Examples from one promising line of investigation employing biochemical mutants are described by Waller. Other papers deal with more specific structural and chemical aspects of development.

Each volume contains an extensive author and subject index, and the general quality of figures, including electron micrograph prints, is excellent. Any laboratory engaged in research on the biochemistry of green plants will need both volumes.

J. A. BASSHAM

## ZOOLOGICAL NEWS

### International Zoo Yearbook

Vol. 7. Edited by Caroline Jarvis. Assisted by Ruth Biegler. Pp. viii + 410 + 61 plates. (London: The Zoological Society of London, 1967.) 126s.

THE Zoological Society of London took a long chance in 1960 when it started the *International Zoo Yearbook*, but the new publication soon got on to its feet, and is now firmly established as a reference book and as a cross-fertilizer between zoos and zoologists.

The seventh volume of the yearbook opens with a section of nineteen papers on penguins in captivity. Penguins in zoos have great popular appeal from their quaint appearance and behaviour rather than their zoological interest. They are difficult to introduce into captivity; the majority of those captured in the wild die before, or soon after, reaching a zoo, but they are paradoxical in that once established the survivors may live for years. Many die of general stress, starvation or thirst on their journey, but the chief killer of newly arrived birds is aspergillosis for which no cure has yet been found. The birds are very susceptible to infection by moulds, and those that survive appear to develop some sort of immunity or resistance through suffering a non-fatal attack. The papers cover the subject thoroughly, and discuss the advantages and drawbacks of internal air-conditioned exhibits compared with outdoor ones, diet, general management, and breeding. Together they form a valuable guide to the care of these birds in zoos.

The second section describes new buildings and exhibits in various zoos of the world—the trend towards protecting indoor exhibits from the public by glass partitions, and outdoor ones by ditches, continues to bring nearer the ideal zoo with only one bar. The display of mixed species of African large mammals at Borås Zoo in Sweden is particularly striking. The largest part of this section, however, consists of papers on the breeding of various species in captivity, mostly during 1965. It presents a remarkable collection of information which contains much of importance not only to the keepers of zoos but to zoologists in general—reports on breeding behaviour, gestation periods, parturition, parental care and other matters. There is a long list of animals that have rarely, or never before, been bred in captivity, from several primates to kiwis and tuataras. Were it not for the yearbook much of this information would go unpublished or would be so scattered in publication that its retrieval would be difficult.

Several articles on conservation and education are included; it is interesting to see that the larger zoos are concentrating more and more on organized educational tours with preliminary lectures, so that a visit to the zoo is directed away from being a casual inspection of queer creatures towards something of permanent value.

The final part of the second section on husbandry and research, like that on breeding, contains much varied and valuable information, including three articles on the dugong in the wild and in captivity. Veterinary matters cover a wide field, from treating paralysed flamingoes to masturbating a rhinoceros into a funnel. Most of the articles here as elsewhere in the yearbook are of high standard, but a few of the shorter anecdotal ones show a lack of knowledge of the literature.

The reference section contains a list of the zoos and aquaria of the world, with particulars of their contents,

staffing, finance and so on, where ascertainable. Interesting lists of animals bred in zoos during 1965, and of zoological and veterinary research recently published or still in progress, also appear. A census of rare animals in the zoos of the world during 1966 is given so that a co-ordinated international breeding policy for rare animals could be drawn up, and inter-zoo matings or exchanges arranged. The criterion of rarity is the list of animals that are rare, or presumed to be rare, drawn up by the International Union for the Conservation of Nature. The recent attempt to breed from the giant pandas now in London and Moscow, which received such wide publicity, shows the action that the census aims at promoting. Stud books for eleven species of rare animals are now established—for some species, such as the wild horse and the wisent, zoos have reversed their usual role as consumers of rare animals and become producers.

The book ends with several appendices, including a dunce's corner in which is posted a list of the zoos that failed to answer questionnaires, or sent no information for the list of rarities. The volume is well produced, and is illustrated with excellent photographs, line drawings and diagrams. Misprints are few, and, although articles from so many contributors vary in quality, the standard required by the Yearbook Advisory Committee is well maintained.

L. HARRISON MATTHEWS

## ADAPTIVE CONTROL

### Theory of Self-Adaptive Control Systems

Edited by P. H. Hammond. (Proceedings of the Second IFAC Symposium, September 14–17, 1965, National Physical Laboratory, Teddington, England.) Pp. xii + 363. (Pittsburgh: Instrument Society of America, 1966. Distributed by Plenum Press, New York.) \$15.

"ADAPTIVE" is a word with different meanings for different people. During the past decade its use has become widespread among control engineers and many papers about adaptive control systems have appeared in the engineering literature. The proceedings of the 1965 Symposium on the "Theory of Self-Adaptive Control Systems" organized by the control engineers' main international organization, the International Federation of Automatic Control (IFAC), contains a fair sample of the types of problem that control engineers have been describing as adaptive.

The original motivation for engineers to become interested in adaptive systems was the need to solve practical problems that were beyond the scope of classical design procedures. Examples of such problems are the design of safe control systems for very high performance military aircraft and the control, for maximum yield or maximum profit, of highly complex industrial chemical processes. These are problems where some piece of information that is required by the classical design procedure is missing, either because of prior uncertainty or because of unpredictable changes in the environment. The idea was that classical controllers might nevertheless be used if they were made with variable parameters that could automatically be adjusted by a signal based on some measurement devised to compensate for the missing information. Various schemes of measurement and compensation have been proposed and two well-defined problems that have emerged are the problem of identifying the dynamics of an unknown system or "black box" and the problem of extremum control or "hill-climbing". These topics account for about half of the thirty-seven papers in the symposium proceedings.

When they were first proposed it seemed obvious that such systems, where a conventional controller is automatically adjusted so as to improve its own performance, should be classified as adaptive. It was soon pointed out, however, that the instrumentation for automatically adjusting the controller was merely an additional feed-

back loop, and that systems described as adaptive and new in principle could equally well be described as multi-loop nonlinear systems that were in principle no different from, although in practice more complex than, conventional feedback control systems. There was considerable controversy about whether the word adaptive could have any specific meaning for control engineers; one suggestion was that a control system was adaptive if its designer regarded it as being adaptive.

The interest of control engineers in adaptive systems was matched by a corresponding interest of applied mathematicians concerned with the mathematical theory of optimal control. The mathematical theory is not always directly applicable to practical engineering problems, but it does provide a basis for defining and classifying different types of control problem. In this context the name adaptive is reserved for the class of control problems where there is some prior uncertainty that can, with advantage, be reduced by observing the performance of the system as it operates: an adaptive system is thus a learning system. Only two papers at the symposium dealt with this well-defined class of adaptive control problems.

One of the attractions of the field of adaptive control systems is the possibility it offers for collaboration between control engineers and biologists. Engineers can offer techniques for analysing and synthesizing adaptive systems; biologists can describe adaptive systems that are more complex, more efficient and more reliable than any known to engineering. There is a section in the proceedings of five papers on adaptive control in biological systems.

Other papers in the proceedings deal with problems that are related to adaptive control problems. It is clear that there is much research in progress under the title of "Adaptive Control" and that this covers a wide range of related problems. These proceedings show that the IFAC symposium was successful in bringing together a variety of these problems and that there is a continuing need for good understanding of the relationships between them.

## PROGRESS OF GAS DYNAMICS

### Rarefied Gas Dynamics

Edited by C. L. Brundin. (Proceedings of the Fifth International Symposium held at the University of Oxford, 1966. *Advances in Applied Mechanics Supplement 4.*) Vol. 1. Pp. xx + 879. \$18.50. Vol. 2. Pp. xx + 881–1731. 148s. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1967.)

THESE two volumes are made up of the written versions of 103 papers read at the Fifth International Symposium on Rarefied Gas Dynamics; all the papers which were read are represented.

The range of topics covered by such a large number of papers must clearly be very wide, so that the two volumes are organized into five sections, four of which commence with a review paper, written by an eminent contributor to the specialized field in question, and designed to give perspective to the research papers which follow. Divisions between sections (and sub-sections) are not rigid and several papers may as well be in one place as another. This fact is representative of the thread of unity which runs through this very interesting and flourishing branch of modern gas dynamics.

The first section, introduced by F. C. Hurlbut, is devoted to an examination of gas-surface interactions. The subject has long been studied from the experimental point of view, especially to obtain information on energy and momentum accommodation coefficients. The need for a deeper understanding of the complexities of the interaction represented by these coefficients has lately led to the development of theoretical models. Both

classical and quantum theories have been used and both will be found among the papers in the first volume together with the latest experimental information.

The second section, on kinetic theory, begins with a concise account of the mathematical status of the Boltzmann equation by J.-P. Guiraud. The mathematical implications of using a simplified model like the linear Boltzmann equation, the Krook equation and the Mott-Smith approach to strong-shock structure are discussed, together with a brief account of applications of the theory. The next nearly six hundred pages bear witness to the continuing activity in this central field of rarefied gas flow research. Topics dealt with include heat transfer, sound propagation, plane-shock-wave structure and free-jet expansions, and it is interesting to speculate on how many more variations can be wrung from the themes originating with Rayleigh, Poiseuille and the anonymous inventors of rotating cylinders, parallel-plate heat-cells and so on. The analytical use of Monte-Carlo methods in this section is notable. Also noteworthy are the theories of free-jet expansion (supported by good experimental evidence) which indicate the directional character of temperature in certain rarefied-gas conditions.

The third section, and the first in the second volume, deals with (so-called) transition-flows. This very difficult area between the continuum and kinetic theory descriptions of gas flow continues to stimulate a large amount of research. The survey article for this section is by J. L. Potter, and includes, among many other things, some interesting remarks on the subject of slender lifting shapes at very high altitudes. There is evidence in the papers presented that new theories are necessary to account for observations of flows near to the leading edge of sharp flat plates in rarefied hypersonic streams. Much new experimental work on this topic is contained in the papers presented at the symposium.

The section devoted to experimental techniques is comparatively short and has no introductory article. Four papers are devoted to molecular beam developments and six more to progress in other areas. The latter includes the use of a laser for direct determination of molecular velocity distribution functions and the laboratory (wind-tunnel) simulation of the radiation resulting from the release of nitric oxide at high altitudes. The latter has yielded an improved rate constant for the chemiluminescent reaction of nitric oxide with atomic oxygen.

The second volume concludes with a total of ten papers on ionospheric aerodynamics (introduction by J. H. de Leeuw) covering, in particular, basic studies of rarefied plasma and plasma-vehicle interactions.

The editor remarks, in the preface, that the published proceedings of previous symposia in the series have become recognized as reference texts. His hope that the current volumes would continue the tradition must be fulfilled, for it would be impossible to ignore these volumes, not least for their very high quality. While reaffirming this view it may be permissible to express some mild misgivings about the manner in which the material is presented. Both volumes reproduce the papers in ordinary typescript, as submitted by the authors, with frequent rendering of mathematical symbols in manuscript. The variety of type faces, allied to the individuality of the authors' hands, does nothing to increase the atmosphere of either unity or legibility in the books. Most papers carry the diagrams and figures at their end, report-style. The result is constant page-turning. Finding the way about the 1,700-odd pages is not aided by the complete absence of any running heads, save, that is, for the pointless repetition of "Rarefied Gas Dynamics". We are told that the mode of presentation was chosen to expedite publication, and no doubt much time has indeed been saved. It could not, however, have taken very much longer for each author to add (say) his name and/or a short title to each typescript sheet with sub-

sequent benefits for the reader navigating his way through the many pages. No account of discussions following presentation of the papers is given (except in two cases) and the editor remarks that it was found that most verbal questions were answered anyway in the written papers; there must be a moral here somewhere.

In conclusion, apart from the criticisms of presentation just voiced, it must be said that this biennial progress report on research into rarefied gas dynamics will surely be included on the (library) shelves of everyone with an interest in the topic.

JOHN F. CLARKE

## TOWARDS A SCIENCE OF MATTER

### The Origins of Chemistry

By Robert P. Multhauf. (Oldbourne History of Science Library.) Pp. 412+9 plates. (London: Oldbourne Book Co., Ltd., 1966.) 70s. net.

No area of the history of science shows more interesting changes at present than does the history of chemistry, as regards both the accumulation of new evidence and the reconsideration of interpretations. For example, we are radically revising our ideas about the role of atomic theory in mid-nineteenth century chemistry; the Industrial Revolution now looks as much chemical as mechanical in inventiveness; the development of European society over long periods becomes more intelligible as more of the influences of chemical thought and production are detected, and so on. As historical detail is increased it becomes important that the surveys of large problems and long periods should be undertaken afresh, so that we can have alternatives to those basic books of the previous generation on which we relied for instruction and reference for so long. Dr Multhauf, director of the Museum of History and Technology in the Smithsonian Institution, has made a new review of the antecedents of chemical science, taking the mid-eighteenth century as his terminus, in a book which can scarcely fail to be widely read and much used.

The book's value is best seen in a comparison of its title with that of a work with which, as Multhauf himself observes, it most nearly invites comparison, Stillman's *The Story of Early Chemistry*, which was conceived forty years ago. Stillman tried to offer a historical narrative; Multhauf properly and wisely offers an enquiry, in the course of which he informs and, every now and again, soberly entertains.

Multhauf's method is different from both Stillman's and Partington's. Stillman was as conscious as a chemical Macaulay of his duty to narrate. Partington, ever suspicious of speculation, insisted so much on the recording of every fact that all sense of movement is lost in the mass of unconsidered, if carefully verified, trifles. Multhauf examines the evidence in a way which will teach the new student how difficult is the art of writing history and how well it can be done by those who care to learn.

Chemistry to Multhauf is one aspect of a science of matter, "an incongruous edifice, a structure erected by independent schools of architecture—philosophers, occultists and chemists—each working largely independent of the others". He sees three main constituents in early chemistry, which have, unfortunately for our understanding, been examined somewhat in isolation. The philosopher finds evidence of theories of ontology, the occultist admires the labyrinthine wisdom of the alchemists, the modern chemist "sees a kind of technological sub-basement from which his illustrious ancestor, Antoine Lavoisier, was finally to emerge". Multhauf attempts to bring these together from the point of view of a historian of chemistry sympathetic to the history of the other two subjects. He claims no new work on manuscripts. Although there is a vast amount of unexamined, unedited material in the great libraries he considers it probable

that enough material for a broad estimate of classical and mediaeval chemistry and alchemy has already reached print. Multhauf does, however, emphasize the work of some people who, in his opinion, have been neglected in the three important stages of the genesis of Greek, Arabic and Latin alchemy, namely, Agathodaimon, Balinus and Ibn Juljul.

Multhauf does not waste space on summaries of well-known works. For example, his account of Geber concentrates on its style and its relation to other works, so that the reader who wants to know a fair amount of what is in the *Summa perfectionis* will have to turn back to Stillman and others. But the reader who reads the *Summa perfectionis* itself will find Multhauf's few pages an excellent stimulus to making his own analysis of its contents.

The same help to understanding of the original works occurs again and again. In the chapter on medical chemistry: "The history of the chemistry of mercury again raises the question of the sense in which we are to suppose that substances were 'known'. By heating mercury in air Geber tells us that he 'coagulates' it, and in the thermal decomposition of the nitrate he 'prepares it most red'. The author of the *De alumnibus* explains similarly the reaction which led him to corrosive sublimate. We can be reasonably confident that we know what was made in these processes, but can we say that the substances were *known* to their 'discoverers'." The ideas of a substance or a pure substance or a chemical species were all to evolve very slowly, to reach certainty only long after the period of this book (and to dissolve again into uncertainty in our own time).

The chapter on which the book hinges has a title which is very congenial to those followers of Collingwood who want to recover the personal experience in past events: "The Rise of the Chemist". Chemistry is what chemists do, and Multhauf emphasizes this in his chapter on the practice of chemistry by individuals and groups in the century before the genesis of scientific chemistry as we know it.

The economic view must also be presented, and Multhauf does this under the two main heads of "Metals" and "Heavy Chemicals". It is a pity that he does not carry his discussion of metals further into the eighteenth century but, because there is no obvious stopping place after Cramer or Réaumur, it is hard to suggest how else this chapter could have been written. If I felt tempted to say the same sort of thing about the chapter on heavy chemicals, it would be because I forgot that the author claims only to discuss "origins". The heavy chemical industry of revolutionary France is a fascinating subject, but it rested on a long past, and it is for this kind of event, which is still so little appreciated, that Multhauf sets out to prepare us.

Multhauf refers in his preface to the increasing professionalization of the study of the history of science. This is a professional's book for professionals, but like so many of the best books of which this can be said, it will bring great pleasure to anyone, scientist or not by occupation, who can claim to be scientifically educated.

FRANK GREENAWAY

## THEORY OF ADHESION

*Treatise on Adhesion and Adhesives*

Edited by Robert L. Patrick. Vol. 1: Theory. Pp. xi + 476. (London: Edward Arnold (Publishers) Ltd.; New York: Marcel Dekker, Inc., 1967.) 175s. net.

IN a broad appreciation of its meaning, the story of adhesives and adhesion has its origin deep in the veils of time. It is clear both by inference as well as by example that man was engaged in its practice long before recorded history. For his many purposes we may presume that he was moderately content with what he believed possible

and with the success achieved and we may also conclude that his materials and techniques assumed horizons which only slowly extended over many thousands of years. During the present century, however, there has been a dramatic upsurge of interest in the subject, as, of course, there has with many others. The nature of adhesives has now been recognized and consequently many new adhesives have appeared; the role of the interface, the character of material defects and many other aspects are beginning to reveal themselves. This coming of age has drawn on and will continue to draw on a wealth of scientific and technological advances so that what was once often regarded as a black art is now beginning to flourish as a scientific discipline. Indeed, I for one would not be surprised if, in the challenge of this technological age, those academic institutions which offer some specialization within their curricula might very well take it upon themselves to include subjects such as adhesion, combining as they do so many experiences at an advanced level. In this way it could promote a native stimulus, other than the examination system, so desirable for a student preparing himself for the great unknown.

The assembly of hitherto specialized knowledge under one cover has meant an increasing trend towards the edited textbook and the *Treatise on Adhesion and Adhesives* is no exception. The present volume is the first of three on the subject under the general editorship of Dr R. L. Patrick. The second volume, to be published in 1968, will be concerned with materials, including adhesives themselves with special topics such as fibre, high temperature and glass-resin adhesion, as well as with brazing, welding and so on. The third volume is to be restricted to applications. The first volume, which relates to theory, opens with a general introduction followed by chapters on intermolecular and interatomic forces, by R. J. Good, adsorption of polymers, by R. R. Stromberg, the mechanisms of adhesion, by J. R. Huntsberger, role of bulk properties of the adhesive, by Turner Alfrey, jun., rheology of polymers used as adhesives, by D. H. Kaelble, fracture mechanics applied to adhesive systems, by G. R. Irwin, variables and interpretation of some destructive cohesion and adhesion tests, by J. L. Gardon, and surface chemistry, by F. M. Fowkes. The author and subject indices are preceded by a list of symbols used in the text.

It would appear that the editor has given his authors a fair amount of licence and yet despite his inference of "angry young men" no suggestion of prejudice or subtle irresponsibility is dominant or even apparent. To a certain extent, as in any textbook, much of the subject matter is available in separate publications and no doubt, because of this, some readers will find some imbalance in the length of chapters. Again, it may cause some surprise that in a book which speaks easily of stress tensors in one chapter, there is a need to define the imaginary unit in another. Others may regard with gloom the dismissal of non-destructive testing. But these are minor criticisms and the editor and authors are to be congratulated on a most interesting and stimulating production, despite some similarity both in title and perhaps less in treatment with another recent publication. The presentation and style are good, diagrams and tables are adequate, and with the exception of one authoritative chapter, references are ample and surprisingly, for a collated textbook, up to date. In view of occasional but slight duplication, I feel that the internal reference system might have been improved but even this works to advantage in promoting a system of self contained chapters. The book will commend itself primarily to physicists, physical chemists and materials scientists as well as new and established researchers in the field of adhesion itself, and although the price, which is perhaps partly a reflexion of the publishers' well placed confidence, will preclude much personal ownership in this country, it will, as it should, find its way onto many bookshelves, and, I hope, into many more laboratories.

R. P. SHELDON

## University News:

**Bradford**  
DR M. G. MYLROI, at present division instrument manager of ICI Fibres, Ltd., has been appointed to the chair of control engineering.

## Newcastle upon Tyne

DR E. J. FIELD has been appointed to a personal chair in experimental neuro-pathology.

## Sheffield

THE following appointments have been made: Mr H. Nicholson, at present lecturer in the Department of Engineering in the University of Cambridge, to the chair of control engineering in the Department of Electronic and Electrical Engineering; Dr F. A. Benson, at present reader in electronics in the university, to the chair of electronic and electrical engineering; Dr B. B. Argent, at present reader in metallurgy in the university, to the newly established third chair of metallurgy; Dr D. S. Munro, at present reader in clinical endocrinology in the university, to a personal chair of clinical endocrinology in the Department of Pharmacology and Therapeutics.

## Appointments

DR A. KELLY has been appointed superintendent of the National Physical Laboratory's newly organized Division of Inorganic and Metallic Structures.

FREDERIC M. PHILIPS has been appointed director of the Office of Public Affairs of the Smithsonian Institution.

THE following appointments have been made in the Office of Scientific Personnel of the US National Research Council: Dr W. C. Kelly has been appointed director of the office in succession to Dr M. H. Trytten; J. C. Boyce will continue to have the responsibility of deputy director and has been given the additional title of director of associateships; Dr E. W. Scott has been appointed director of special international programmes in succession to S. S. Steinberg.

**CORRIGENDUM.** In Table 1 of the article "Transplantable Mouse Neoplasm Control by Neutron Capture Therapy", by Lee E. Farr and T. Konikowski (*Nature*, 215, 550; 1967), the heading of the first column should read "Neutron flux  $\text{cm}^2 \times 10^{12}$ ".

**ERRATUM.** In the communication entitled "Photochemical Oxidation of Neptunium(V) by Xenon Trioxide" (*Nature*, 215, 732; 1967) the first sentence of the second paragraph

should read: "The neptunium(V) was prepared by solution of neptunium dioxide in concentrated perchloric acid and reduction of the resulting neptunium(VI) to neptunium(V) with hydrogen peroxide". The third sentence of the same paragraph should read: "The ionic strength was maintained constant at 2 molar with lithium perchlorate which was recrystallized six times before use". Reference 2 should be to Koch and Williamson, not Koch and Williams, and reference 4 should be to Cleveland, J. M., *Inorg. Chem.*, 6, 1302 (1967). The spectrophotometer used was GE No. PH/18A/T10P-6V (CPR).

# CORRESPONDENCE

## Voyager Experiments

SIR,—In 1973 the National Aeronautics and Space Administration proposes to conduct the first of the Voyager series of missions to Mars, using the Saturn launch vehicle. We wish to call the attention of the scientific community to the opportunity of proposing experiments for this initial flight.

The primary objectives of the 1973 Voyager Mars mission are to obtain information relevant to the existence and nature of extraterrestrial life; the atmospheric, surface and body characteristics of the planet; and the planetary environment. Orbital reconnaissance, direct measurements during atmospheric entry, and investigations after soft-landing on the Martian surface are part of the mission.

As you may know, funding for the Voyager Program is under formal consideration at the present time by the US Congress, and final funding authority has not yet been obtained for proceeding with Voyager in Fiscal Year 1968. Regardless of the level of funding support obtained for Voyager this fiscal year, it is our plan to begin evaluating scientific proposals on November 1, 1967, and to select scientists for participation in the planning and development steps by February 1968.

Approximately 5,000 copies of the formal announcement have been mailed to scientists on August 9, 1967. If others are interested, additional copies may be obtained from Dr Robert F. Fellows, Code SY, Voyager Program Scientist, NASA Headquarters, Washington, D.C. 20546.

Yours faithfully,

HOMER E. NEWELL

Associate Administrator for Space Science and Applications.

## APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

**SENIOR LECTURER/LECTURER** (with a degree in psychology and a main interest in experimental psychology) in the **APPLIED PSYCHOLOGY DEPARTMENT**—The Staff Officer (ref. 582/2), The University of Aston in Birmingham, Gosta Green, Birmingham, 4 (August 24).

**ASSISTANT LECTURER or LECTURER in SOCIAL ADMINISTRATION** in the **DEPARTMENT OF SOCIOLOGY**—The Secretary, The University, Aberdeen (August 26).

**LECTURER** (with good academic qualifications and preferably some teaching experience) in **EDUCATIONAL PSYCHOLOGY/PHILOSOPHY** in the Institute of Education—The Registrar, The University of Keele, Keele, Staffordshire (August 26).

**RADIATION OFFICER** (graduate preferably with a knowledge of radiation protection and electronics) in the **DEPARTMENT OF PHYSICS**—The Registrar, The University of Manchester, Manchester, 13, quoting Ref. 120/67/Na (August 26).

**RESEARCH ASSISTANT** (preferably with an interest or training in electrophysiology, statistical methods or biochemical techniques) in the **DEPARTMENT OF ZOOLOGY** to work with Dr D. M. Guthrie on the physiology of invertebrate nervous systems—The Secretary, The University, Aberdeen (August 26).

**TEMPORARY DEMONSTRATOR/ASSISTANT LECTURER or LECTURER** (preferably with an interest in plant physiology or plant biochemistry) in **BOTANY** at the Hartley Botanical Laboratories—The Registrar, The University of Liverpool, Liverpool, 3, quoting Ref. RV/120/N (August 26).

**SENIOR GRADE PHYSICIST** (with hospital physics experience and preferably experience in therapeutic and diagnostic uses of unsealed isotopes)—Dr H. Miller, Chief Physicist, Regional Medical Physics Department, 21 Claremont Crescent, Sheffield, 10 (August 29).

**CHAIR OF INDUSTRIAL ENGINEERING**—The Assistant Registrar, The College of Aeronautics, Cranfield, Bedford (August 31).

**LECTURER in PHYSICS** to pursue research in experimental high energy physics—The Registrar, University of Manchester, Manchester, 13, quoting Ref. 119/67/Na (August 31).

**LECTURER, SENIOR LECTURER or READER** in the **DEPARTMENT OF SOCIAL AND PREVENTIVE MEDICINE**—The Registrar, The University of Manchester, Manchester, 13, quoting Ref. 125/67 (August 31).

**RESEARCH ASSISTANT** (with a good honours degree and interests in plant ecology, genetics or mineral nutrition) in the **SCHOOL OF PLANT ECOLOGY**, to investigate the use of plant populations tolerant to toxic metals for the reclamation of toxic mine waste—The Registrar, University College of North Wales, Bangor, North Wales (August 31).

**SENIOR LECTURER in the DEPARTMENT OF SOCIAL AND PREVENTIVE MEDICINE**—The Registrar, The University of Manchester, Manchester, 13, quoting Ref. 126/67 (August 31).

**LECTURER** (preferably with a first degree and postgraduate training to Ph.D. level in plant physiology, biochemistry or biophysics) in **PLANT PHYSIOLOGY** in the **DEPARTMENT OF PHYSIOLOGY AND ENVIRONMENTAL STUDIES**—The Registrar, The University, Nottingham (September 1).

**RESEARCH TECHNICIAN** (with experience in histology) in the **UNIVERSITY DEPARTMENT OF ORTHOPAEDIC SURGERY** to work on histo-biochemistry of bone and joint tissues with special interest in Paget's disease—The Secretary, Board of Governors, United Manchester Hospitals, Manchester, 13 (September 2).

**ASSISTANT LECTURER or LECTURER** (with particular interests in economic geology or in fields related to engineering geology) in **APPLIED GEOLOGY**—The Registrar, University of Sheffield, Sheffield (September 4).

**ASSISTANT LECTURER** (preferably wishing to develop an interest in either industrial microbiology, electron microscopy, microbial genetics, or protozoology) in **MICROBIOLOGY** in the **DEPARTMENT OF BIOLOGICAL SCIENCE**—The Academic Registrar (LFG), University of Surrey, Battersea Park Road, London, S.W.11 (September 4).

**ASSOCIATE PROFESSOR OF PSYCHOLOGY** at Macquarie University—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; or The Registrar, Macquarie University, Eastwood, New South Wales, Australia (Australia and London, September 4).

**LECTURER or ASSISTANT LECTURER** in the **DEPARTMENT OF ANATOMY**, University of Singapore—The Inter-University Council, 33 Bedford Place, London, W.C.1 (September 7).

**BIOCHEMIST**, initially Scientific Officer Grade, in the **PHYSIOLOGY AND BIOCHEMISTRY DEPARTMENT** to join a group engaged in fundamental research into the metabolism of normal and diseased poultry—The Secretary, Houghton Poultry Research Station, Houghton, Huntingdon (September 8).

**SCIENTIFIC OFFICER** (with a good honours degree and postgraduate research experience) at Moor House Field Station for studies on primary production and nutrient circulation in blanket bog—Dr O. W. Heal, Merlewood Research Station, Natural Environment Research Council, Grange-over-Sands, Lancashire (September 8).

**SENIOR LECTURER or LECTURER in BIOCHEMISTRY** in the **DEPARTMENT OF BIOLOGY AND CELL SCIENCE**—The Clerk to the Governors, Woolwich Polytechnic, London, S.E.18 (September 8).

**TEMPORARY LECTURER in CLINICAL PSYCHOLOGY** at the University of Western Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 10).

**LABORATORY SUPERINTENDENT**—The Secretary, School of Agriculture (University of Nottingham), Sutton Bonington, Loughborough (September 15).

**LECTURER in GEOLOGY and GEOGRAPHY** at the University of Natal, Pietermaritzburg—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, September 15).

**RESEARCH ASSISTANT in the DEPARTMENT of BOTANY** to work under the direction of Professor K. Wilson on algal cell-wall structure and growth—The Secretary, Royal Holloway College (University of London), Englefield Green, Surrey (September 15).

**LECTURER** (with a higher degree, preferably a Ph.D. in psychology and measurement in education, or in educational psychology) in **EDUCATIONAL PSYCHOLOGY** at the University College of Townsville, University of Queensland—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 18).

**CHIEF TECHNICIAN or SENIOR TECHNICIAN** (with H.N.C., Final City and Guilds, A.T.M.L.T., F.I.M.L.T., or equivalent qualification) in **HUMAN BIOLOGY**, University of Zambia—The Inter-University Council, 33 Bedford Place, London, W.C.1 (September 20).

**LECTURER** (graduate in pharmacy and preferably holding the degree of Ph.D.) in **PHARMACY** at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, September 22).

**SENIOR TUTOR-DEMONSTRATOR in GEOGRAPHY** at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 22).

**CHAIR OF PHYSIOLOGY** at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 29).

**LECTURER in PHILOSOPHY**; and a Lecturer (qualified in economic, urban or social geography, and preferably an interest in the application of quantitative techniques in geography) in **GEOGRAPHY** at Flinders University of South Australia—The Secretary-General, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; or The Registrar, Flinders University of South Australia, Bedford Park, South Australia (September 29).

**LECTURER in PHYSICS** at Monash University—The Academic Registrar, Monash University, Clayton, Victoria, Australia; or the Secretary-General, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (September 29).

**POSTDOCTORAL FELLOW** (with a Ph.D. or equivalent degree in physical chemistry or chemical engineering) in **CHEMICAL ENGINEERING** at the University of Canterbury, Christchurch, New Zealand, to carry out full-time research on the thermodynamics of gaseous and liquid mixtures—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (September 30).

**SENIOR LECTURER/LECTURER** (preferably with qualifications in economics including agricultural economics and forestry) in **FOREST ECONOMICS AND FOREST MANAGEMENT**, University of Melbourne—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 30).

**HEAD** (of professional standing or its equivalent, and high veterinary, medical or biological qualifications) of the **ANIMAL DIVISION**—Sir Peter Medawar, F.R.S., National Institute for Medical Research, Mill Hill, London, N.W.7 (October 2).

**CHAIR OF MATHEMATICAL PHYSICS** (preference will be given to candidates whose work is in the field of theoretical quantum physics)—The Registrar, University Registry, The Old Schools, Cambridge (October 21).

**ASSISTANT PROFESSOR or ASSOCIATE PROFESSOR** (interested in cardiovascular pharmacology or biochemical pharmacology) in the **DEPARTMENT OF PHARMACOLOGY**—Professor G. B. Frank, Department of Pharmacology, University of Alberta, Edmonton, Alberta, Canada.

**IMMUNOLOGIST/ZOOLOGIST** (preferably with some immunological experience) for an active research programme in the A.R.C. Cattle Blood Typing Service—The Secretary, A.R.C. Animal Breeding Research Organization, West Mains Road, Edinburgh, 9.

**POSTDOCTORAL FELLOW** (preferably with some experience in magnetochemistry) in the **DEPARTMENT OF INORGANIC AND STRUCTURAL CHEMISTRY**—Professor H. Irving, Department of Inorganic and Structural Chemistry, The University, Leeds, 2.

**PRINCIPAL SCIENTIFIC OFFICER and a SENIOR SCIENTIFIC OFFICER** (citizens of and permanently resident in the United Kingdom or the Republic of Ireland, with a degree in zoology, preferably honours, or a medical degree, and postgraduate research experience in tropical parasitology) at the East African Institute for Medical Research, Mwanza, Tanzania, to plan and carry out research on schistosomiasis and methods of control, and also to train newly appointed science graduates in research methods—The Ministry of Overseas Development, Room 403, Eland House, Stag Place, London, S.W.1.

**PRINCIPAL TECHNICIAN in the DEPARTMENT OF ZOOLOGY** to be in charge of the chemistry teaching laboratories and to be responsible for the supervision of all first-year teaching laboratories in a new building to be ready for occupation in 1969—The Administrator, Department of Zoology, University of Oxford, Parks Road, Oxford.

**RESEARCH ASSISTANTS** (with a first- or second-class (upper or lower) honours degree) in **PHYSICS** to undertake postgraduate research leading to M.Phil. or Ph.D. internal degrees of the University of London—Head of the Department of Physics, Sir John Cass College, Jewry Street, London, E.C.3.

**SENIOR or JUNIOR RESEARCH ASSISTANT in INSECT PHYSIOLOGY** in the **SCHOOL OF BIOLOGICAL SCIENCES**, to join a research project in the field of water relationships—The Administrative Assistant, School of Biological Sciences, University of East Anglia, Wilberforce Road, Norwich, NOR. 77H, quoting Ref. N-X.

**SENIOR TECHNICIAN or TECHNICIAN** (preferably with experience with the electron microscope or in cell biology) to assist in research on the fine structure and function of plant cells—Mr. A. D. Greenwood, Botany Department, Imperial College of Science and Technology, London, S.W.7.

**TECHNICIAN** (preferably with a knowledge of physiological and/or biochemical techniques and experience in another teaching department) in the **DEPARTMENT OF ZOOLOGY** to assist with the preparation of laboratory classes and help with research work—The Deputy Secretary, The University, Southampton.

**ZOOLOGIST** (with ecological interests) to complete a team of Dutch and British freshwater biologists working at Tjeenkemeer in Holland—The Registrar, University of Liverpool, Liverpool, quoting Ref. RV/130/N.

## HOW TO BUY NATURE

Volumes start in January, April, July and October, but subscriptions may begin with any issue.

The direct postal price per subscription for one or two copies of NATURE each week is:

### \*12 MONTHS (52 issues and 4 indexes)

Great Britain and Eire.....	£14.0.0 each
United States of America.....(by air freight).....	\$44 each
Canada.....(by air freight).....	\$47.80 each
Elsewhere overseas by surface mail.....	£13.15.0 each

(Charge for delivery by air mail on application)

\*Shorter periods *pro rata*. (Minimum three months.)

### MULTIPLE SUBSCRIPTIONS

For subscribers who take more than two copies of NATURE each week these reduced annual rates are offered:

#### 12 MONTHS (52 issues and 4 indexes)

Number of Copies	G.B. & Eire	U.S.A. (by air freight)	Canada (by air freight)	Elsewhere (surface mail)
3-5	Each £13.10.0	Each \$42	Each \$46.00	Each £13.10.0
6-11	£12.15.0	\$40	\$43.60	£12.15.0
12 or more	£12.0.0	\$38	\$41.70	£12.0.0

Multiple subscriptions must run concurrently. Every copy will be posted separately, and for speed of delivery each subscription can be addressed to a different individual, or department at the same address. (ZIP essential for U.S.A.)

### APPOINTMENTS VACANT

#### MACQUARIE UNIVERSITY SYDNEY, AUSTRALIA

Applications are invited for the following positions within the

#### SCHOOL OF MATHEMATICS AND PHYSICS

**ASSOCIATE PROFESSOR.** Candidates for the position of Associate Professor should have had extensive experience in teaching physics at advanced undergraduate level. Applications will be particularly welcome from those with special knowledge of solid state physics.

**SENIOR LECTURERS/LECTURERS.** For the positions of Lecturer or Senior Lecturer, applications will be particularly welcome from those with interest in modern algebra, probability and measure theory or in experimental biophysics, chemical physics or solid state physics.

**SENIOR TUTORS/TUTORS.** For the positions of Tutor or Senior Tutor, applicants should have suitable qualifications for conducting tutorials in first and second year mathematics or physics and to carry out associated duties.

The salary for an Associate Professor is \$A8,600 per annum. The salary for a Senior Lecturer will be within the range \$A6,600 by \$A200 to \$A7,600 per annum; and for a Lecturer \$A4,800 by \$A220 to \$A6,340 per annum. The salary for a Senior Tutor will be within the range \$A4,200 by \$A200 to \$A6,000 per annum; and for a Tutor \$A3,000 by \$A160 to \$A3,800 per annum. Academic salaries are at present under review. There is a housing scheme and provision is made for superannuation and study leave.

Macquarie University occupies an attractive site on the outskirts of metropolitan Sydney, and is planned to develop rapidly over the next decade. The University is organized on a School system, which provides considerable flexibility in the construction of degree courses for the individual student. The University commenced postgraduate teaching in 1966 and undergraduate teaching this year. Some 1,200 students are currently enrolled in the University including approximately 100 postgraduate students. Courses are offered to full-time, part-time and external students.

Details of the University's plans for development and the method of application may be obtained from the Secretary-General, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or from the Registrar, Macquarie University, Eastwood, New South Wales, Australia. Applications close in Australia and London on September 4, 1967. (618)

#### HOUGHTON POULTRY RESEARCH STATION

(Financed jointly by the Agricultural Research Council and the Animal Health Trust)

#### PHYSIOLOGY AND BIOCHEMISTRY DEPARTMENT

Vacancy for an additional **BIOCHEMIST** interested in joining a group engaged in fundamental research into the metabolism of normal and diseased poultry. Projects include the influence of stress and nutritional status on metabolic activity, the control of carbohydrate and lipid metabolism by hormones and intermediary metabolites, and the mechanism of thermoregulation. Opportunity to work for a higher degree. Initial appointment in the Scientific Officer grade, starting salary according to age, qualifications and experience in the scale £926 to £1,574 per annum. Promotion from this grade would be to that of Senior Scientific Officer (£1,744 to £2,155 per annum). The post is permanent and pensionable under F.S.S.U.

Further particulars and application forms from the Secretary, Houghton Poultry Research Station, Houghton, Huntingdon, to whom completed application forms should be returned by September 8, 1967. (543)

# Physicists for Research & Development

The Pilkington Group, World Leader in the Glass Industry, wants men and women aged 23-35 with Degree, Technical or Professional qualifications in Physics for vacancies in Research and Development. The programme of work includes:

1. Electrical conductivity and dielectric properties of glass.
2. Radio interference and switching surge performance of High Voltage insulators.
3. Heat transfer applied to glass melting problems.
4. Annealing, toughening and cutting of glass.
5. Problems of fluid dynamics and thermodynamics.
6. Use of gas lasers in the investigation of velocity flows, holography and general optical testing.
7. Use of model techniques to study the behaviour of glass at high temperatures.
8. Further development of the Float Process.

Please write for application form, quoting reference RDP/1, to D. W. L. Burnham, Personnel Officer (Graduate Recruitment), Pilkington Brothers Limited, St. Helens, Lancashire.

# PILKINGTON

(635)

## ROCHE

### SPECIALIST IN SEPARATION TECHNIQUES

An investigation team (at our Laboratories in Welwyn Garden City, Hertfordshire), performing diagnostic studies related to Process improvement, is seeking a man to specialise in separation techniques.

The successful candidate will investigate new chromatographic separation techniques and instruments, and will assist with departmental problems where these involve separation problems.

The man appointed will have an assistant, whose work will include the maintenance of chromatographic equipment and all apparatus used for purification and separation techniques.

The suitable applicant would be a primary graduate, or a man with a qualification such as L.R.I.C. or Grad.R.I.C. Experience in the fields of chromatography and/or electronics would be an advantage. The Department is housed in new modern laboratories and the working conditions are excellent.

Salary will depend on age and experience, and all other Conditions of Service are good. Write, for an Application Form and booklet on our Company, to the Assistant Staff Officer at:

**ROCHE PRODUCTS LIMITED**  
15 MANCHESTER SQUARE LONDON W1

(630)

**NEW ZEALAND**

Wellington Hospital Medical Unit

J. R. McKENZIE RESEARCH FELLOW  
IN BIOCHEMISTRY**Interesting position for  
BIOCHEMIST**

Suitably qualified Science Graduate required for position as Biochemist to Wellington Hospital Medical Unit, undertaking clinical research in lipid field and major epidemiological cardiovascular surveys among Polynesians in Pacific and New Zealand in 1968-69. Return fare United Kingdom for appointee and family after three years' service. Preference for Ph.D. or M.Sc. with experience in lipid carbohydrate metabolic field, a sense of adventure, and a desire to visit Pacific islands. Commencing salary within scale NZ\$3,350 to NZ\$4,730.

For conditions of appointment apply Professor W. J. H. Butterfield, Department of Medicine, Guy's Hospital, London, S.E.1. (626)

**SHEFFIELD NO. 3 GROUP  
OF HOSPITALS**REGIONAL MEDICAL PHYSICS  
DEPARTMENT**SENIOR GRADE PHYSICIST**  
(£1,833 to £2,276)

Hospitals physics experience essential. Experience in therapeutic and diagnostic uses of unsealed isotopes an advantage.

Application forms and further details from Dr. H. Miller, Chief Physicist, Regional Medical Physics Department, 21 Claremont Crescent, Sheffield 10. Tel. 64481. Closing date August 29, 1967. (537)

**UNIVERSITY OF LEEDS****DEPARTMENT OF  
PHARMACOLOGY**

Applications are invited from candidates qualified in an appropriate science or in medicine for the post of LECTURER OR ASSISTANT LECTURER IN PHARMACOLOGY in the Department of Pharmacology. Duties may include teaching medical, dental and science students. Good facilities for research. Salary on the scale £1,470 to £2,630 (efficiency bar £2,270) or £1,900 to £2,750 (efficiency bar £2,510) (if medically qualified) or £1,105 to £1,340 for an Assistant Lecturer or £1,470 to £1,630 (if medically qualified). Initial appointment at any point on the scale.

Applications (three copies), stating age, qualifications and experience and naming three referees, should reach the Registrar and Secretary, The University, Leeds, 2 (from whom further particulars may be obtained) not later than September 18, 1967. (593)

**UNIVERSITY OF SURREY****DEPARTMENT OF BIOLOGICAL SCIENCES**  
**ASSISTANT LECTURER IN MICROBIOLOGY**

Applications are invited for the post of Assistant Lecturer to assist in the teaching of students preparing for the B.Sc. Honours Degree in Microbiology, and to participate in the research work of the Department. Preference may be given to applicants wishing to develop an interest in either Industrial Microbiology, Electron Microscopy, Microbial Genetics, or Protozoology. Salary Scale: £1,105 to £1,340 per annum, plus £60 London Allowance.

Further particulars from the Academic Registrar (LFG), University of Surrey, Battersea Park Road, London, S.W.11, to whom applications, naming not more than three referees, should be sent by September 4. (620)

**PUBLIC SERVICE OF TASMANIA,  
AUSTRALIA****RESEARCH-LIAISON HORTICULTURIST**

DEPARTMENT OF AGRICULTURE

Applications are invited for appointment to a position of Research-Liaison Horticulturist in the Horticultural Division of the Department of Agriculture, Tasmania.

**LOCATION: Hobart.**

**SALARY RANGE:** Class II. \$A5,439-\$A5,583-\$A5,868-\$A6,153 per annum.  
Class III. \$A6,432-\$A6,708-\$A7,005-\$A7,305 per annum.

Commencing salary will be according to qualifications and experience, and will be payable from date of embarkation for Australia.

**DUTIES:** The appointee will be required to provide liaison between the Horticultural Division and other Divisions of the Tasmanian Department of Agriculture engaged on horticultural, entomological, and plant pathological and extension research. Preparation of bulletins, pamphlets, press releases, radio and television broadcasts, field day material, and replies of a technical nature. Supervision of field demonstration trials within the Horticultural Division.

**QUALIFICATIONS:** A degree in Agricultural or Horticultural Science or equivalent university degree. Applicant should have had at least five years research or extension experience in horticultural crops, particularly fruit and vegetables. An interest in journalism, radio and television work.

Passages from the United Kingdom are provided under the Commonwealth Migration—Assisted Passage—Scheme, arranged through the Agent General for Tasmania. In addition, further assistance with passages and freight charges, etc., is available.

Recreation leave, sick leave, and long service leave are provided.

Superannuation is compulsory for permanent officers.

Enquiries for application forms should be addressed to the **Agent General for Tasmania, 458/9 Strand, London, W.C.2.**

(623)

**UNIVERSITY OF MANCHESTER  
INSTITUTE OF SCIENCE AND  
TECHNOLOGY****TECHNICIAN/SENIOR TECHNICIAN**

A Technician/Senior Technician is required in the Department of Chemistry to work with a new section working on Gas Electron Diffraction. The work involves the building of laboratory apparatus, the running of a photographic dark-room, and assistance with the maintenance and running of the electron diffraction machine. Although some chemical knowledge is desirable, greater emphasis will be placed on interest in and skill in handling electrical, optical and mechanical equipment. Applicants should be over 21 years of age. Salary scales, Senior Technician: Within the scale £912 to £1,230 per annum according to qualifications and experience. Technician: Within the scale £653 to £1,018 per annum, according to qualifications and experience. Five-day, 37½-hour week. Superannuation Scheme. Canteen facilities.

Requests for Application Forms quoting Reference Number CH25 should be sent to the Bursar. The University of Manchester, Institute of Science and Technology, Room M2, Velvet House, Sackville Street, Manchester 1. Completed forms to be returned within seven days of the appearance of this advert. (594)

**UNIVERSITY OF SYDNEY****SENIOR TUTOR-DEMONSTRATOR IN  
GEOGRAPHY**

Applications are invited for the above-mentioned position. The successful applicant will be required to conduct, or assist in, courses in human and/or physical geography; and to assume some major responsibility in the operation of first-year practical classes. Preference will be given to candidates with previous experience in research, the handling of practical classes, and especially in the supervision of demonstration staff. Salary for a Senior Tutor-Demonstrator is within the range \$A4,200 by \$A200 to \$A6,000 per annum. Academic salaries are at present under review.

Information concerning superannuation, housing scheme, sabbatical leave, etc., and method of application is obtainable from the Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1. Applications close in Australia and London on September 22, 1967. (619)

**BREWING  
RESEARCH**

A well qualified **Microbiologist** or **Biochemist** is required for Whitbread's Group Research Laboratory. The successful candidate will undertake research on yeast and fermentation and will be responsible for maintaining a yeast culture collection.

Please reply, with full details of age, qualifications and experience, to:

**Chemist-in-Charge,  
Research Laboratory,  
Whitbread & Co. Ltd.,  
Chiswell Street, London, E.C.1.**

(606)

**ORGANIC CHEMIST  
PH.D.**

An Organic Chemist is required to work on the synthesis of photo-active compounds in our Research Laboratories at Hatfield. Previous research experience is essential and candidates should preferably possess a Ph.D.

Please reply to:  
The Personnel Manager (Ref. 18),  
**HAWKER SIDDELEY DYNAMICS  
LIMITED,  
Hatfield, Herts.**

(511)

# A Bacteriologist

is required in the microbiology section of the Wantage Research Laboratory of the UNITED KINGDOM ATOMIC ENERGY AUTHORITY. He will be concerned with studies on the radiation sensitivity of bacteria, and his work will be in support of the use of ionizing radiation for the sterilization of medical equipment and the preservation of food; this topic involves contact both with industry and with other laboratories in the U.K. and abroad. Excellent irradiation facilities are available and there is close cooperation with teams working in biology and chemistry.

## QUALIFICATIONS AND EXPERIENCE:

The appointment will be made in either the Scientific Officer or the Senior Scientific Officer grade, and applicants should have a first- or good second-class honours degree in a biological science and experience in microbiology.

## SALARY:

The starting salary will be within the range £955-£1,685 (Scientific Officer) or £1,870-£2,310 (Senior Scientific Officer) and will be related to qualifications and experience.

HOUSING : SUPERANNUATION

For application forms please write, quoting reference A.5207/34, to:

**The Personnel Department,  
U.K.A.E.A.  
Atomic Energy Research Establishment  
Harwell, DIDCOT, Berks.**

(592)

**LOUGHBOROUGH  
UNIVERSITY OF  
TECHNOLOGY**

## RESEARCH POSTS

The Department of Ergonomics and Cybernetics has vacancies for Research Fellows, Mature Research Students, or Research Students to work in the following areas:

Dynamic anthropometry — body dimensions and functional space requirements.

Mobility problems of the disabled including treatment of survey data, functional assessment and determination of body dimensions, and ergonomics of wheelchair design.

Behaviour in stress situations, especially fire and explosions.

At least one post will require knowledge of mechanical engineering.

Salaries within scales:

Research Fellow, £1,470 by £90 to £1,740.

Mature Research Student, £1,070 by £80 to £1,310.

Research Student, £500 per annum tax free with certain supplementary allowances.

For further details write to Head of Department.

Loughborough

Leicestershire

(634)

## SCIENTIFIC RESEARCH COUNCIL, JAMAICA PRINCIPAL SCIENTIFIC OFFICERS

Applications are invited from qualified and experienced persons for posts of Principal Scientific Officer in the Scientific Research Council, Jamaica, to supervise research in the Bioresources and Mineral Resources Sections. The holders of these posts will be section leaders and should possess wide experience in research and the ability to inspire and supervise staff.

Applicants for the post in the Bioresources Section should have a Ph.D. in Biochemistry or Organic Chemistry, or have had relevant postgraduate research experience of equivalent standard and duration supported by satisfactory evidence of research ability.

Applicants for the post in the Mineral Resources Section should have a Ph.D. in Geochemistry, Inorganic Chemistry or Ceramics, or have had relevant postgraduate research experience of equivalent standard and duration supported by satisfactory evidence of research ability.

The salary scale of the post of Principal Scientific Officer is £2,100 by £75 to £2,400 per annum. The maximum salary of £2,400 per annum plus special personal and housing allowances totalling £1,600 per annum will be paid to successful applicants depending on experience and qualifications. Appointments will be on contract for two or three years with a 20 per cent gratuity on satisfactory termination of contract.

Applications in writing, giving full curriculum vitae and the names of three referees, should be sent not later than September 30, 1967, to the **Technical Director, Scientific Research Council, P.O. Box 502, Kingston, Jamaica**, from whom further particulars of the posts may be obtained.

(607)

UNIVERSITY OF SUSSEX

## RESEARCH ASSISTANT

Applications are invited for a post of RESEARCH ASSISTANT in the Experimental Psychology Laboratory for a research project on long- and short-term memory.

The appointment is available from October, 1967, at an initial salary of £800 per annum.

Apply (three copies) stating age, qualifications, research interests and experience, together with the names of three referees, as soon as possible to the Assistant Registrar (Establishment), the University of Sussex, Essex House, Falmer, Brighton, quoting Ref. 937/1.

(597)

UNIVERSITY OF ALBERTA

EDMONTON, ALBERTA, CANADA

## DEPARTMENT OF PHARMACOLOGY

Applications are invited for the post of Assistant Professor or Associate Professor in the Department of Pharmacology from persons interested in Cardiovascular Pharmacology or Biochemical Pharmacology. The salary scale attached to this position is \$9,000 to \$12,450 for an Assistant Professor or \$12,500 to \$16,550 for an Associate Professor. The commencing salary will depend on the qualifications and experience of the successful applicant.

Further particulars of the position and of the concomitant amenities such as travelling expenses on first appointment and pension scheme may be obtained from Professor G. B. Frank, Department of Pharmacology.

(513)

UNITED LIVERPOOL HOSPITALS

## DEPARTMENT OF CHEMICAL PATHOLOGY

Applications are invited from suitably qualified candidates, for the post of SENIOR BIOCHEMIST to assist with the Department's routine work and research programme, particularly in relation to the metabolic ward at the Liverpool Royal Infirmary. The salary scale is £1,833 rising by annual increments (5) to £2,276 per annum. Whitley Council Conditions of Service apply.

Applications, stating age, qualifications, previous experience and the names of three referees should be sent by September 1, to the Secretary, 80 Rodney Street, Liverpool 1.

(628)

## UNIVERSITY OF SURREY TECHNICIAN (CHEMISTRY DEPARTMENT)

Applications are invited from persons aged 21 and over, preferably with City and Guilds or I.S.T. qualifications, for the post of Technician to assist in the teaching and research laboratories of the Chemistry Department. Good holidays and conditions; 37½ hour week; contributory superannuation scheme. Salary at an appropriate point in the scale £683 to £968 per annum plus £60 London Allowance.

The post will initially be at Battersea but will transfer to the new University buildings at Guildford in 1969. Substantial assistance will be given towards travelling expenses from the Guildford area.

Application forms may be obtained from the Staff Officer, University of Surrey, Battersea Park Road, London, S.W.11.

(640)

## EDINBURGH SCHOOL OF AGRICULTURE

### LECTURER IN AGRICULTURAL BIOCHEMISTRY—Grade III

### ASSISTANT ADVISORY NUTRITION CHEMIST—Grade IV

Applications are invited for the above posts.

Applicants should possess an Honours degree in Biochemistry, Agricultural Chemistry or equivalent.

Salary scales: Grade III, £1,396 to £2,193  
Grade IV, £926 to £1,277

Further particulars and application form from Secretary, The Edinburgh School of Agriculture, West Mains Road, Edinburgh, 9.

(602)

**B.F.M.I.R.A.**

Applications are invited to fill a number of vacancies for Scientific Staff in various key areas of the Research Association's activities.

**Membership Services Advisory Officer**

A scientist with experience in food manufacture and technology is required to handle inquiries from manufacturers seeking advice from the R.A.

**Indexer/Abstractor**

The successful applicant will work on information retrieval and production of monthly abstracts. Previous experience is not required. Scientific experience and a knowledge of German is an advantage.

**Biochemist**

An investigation into non-enzymic oxidative reactions and textural changes in fruit and vegetables is supported by an Agricultural Research Council grant. This is a 3-year project suitable for a higher degree. Applicants should hold a good honours degree.

**Assistants**

There are good opportunities for young applicants of approximately A-level or H.N.C. standards in Chemistry, Physics, or Microbiology to enter as Scientific Assistants or Assistant Experimental Officers, depending on qualifications.

Competitive salaries will be offered for all posts.

Apply to:

Director of Research,  
The British Food Manufacturing  
Industries Research Association,  
Randalls Road,  
Leatherhead,  
Surrey.

(613)

**UNIVERSITY OF SUSSEX****THE CHEMICAL LABORATORY  
MICROANALYST**

There is a vacancy for an experienced MICROANALYST to take charge of the Microanalytical Laboratory. This position is graded in the Chief Technician salary range of £1,242 to £1,423 per annum.

Apply, giving the names and addresses of two referees, a brief résumé of previous experience, qualifications and age, as soon as possible, to The Laboratory Superintendent, Chemical Laboratory, The University of Sussex, Falmer, Brighton, BN1 9QJ, quoting Ref. 940/2. (598)

**BATH UNIVERSITY OF TECHNOLOGY**

Applications are invited for a

**SENIOR LECTURER**

in the School of Materials Science. This is a new post arising from the development of the School and suitably qualified established workers in the field of physics or physical chemistry having interests in the study of new materials may be interested.

Salary in the range £2,520 to £3,310. F.S.S.U.

Further particulars and application forms obtainable from the Registrar (S). The University, Bath, please quote reference 67/93. (610)

**IMPERIAL COLLEGE**

Opportunities for postgraduate and postdoctorate research in a large group concerned with physico-chemical properties of materials at elevated temperatures. Specific projects include: (1) Electrochemical and electronic properties of solid oxides; (2) Chemical stability of oxy-carbide and dispersed phase materials. Applicants should possess an Honours Degree in an appropriate subject and for the postdoctorate post either a higher degree or appropriate research experience.

Applications to Professor C. B. Alcock, Metallurgy Department, Imperial College, S.W.7. (570)

**Scientific Civil Service****RESEARCH FELLOWSHIP****MINISTRY OF DEFENCE  
(ARMY DEPARTMENT)****MICROBIOLOGICAL RESEARCH ESTABLISHMENT**

Porton Down, Salisbury, Wilts.

**SENIOR or JUNIOR RESEARCH FELLOW** in the **Experimental Pathology Section** to work on the pathology of virus encephalomyelitis. Programme would relate to work being carried out both in the Virus Section, and in the Epidemiology Section on the transmission of and infection with arboviruses.

**QUALIFICATIONS:** A good honours degree in Medicine or in Veterinary science or equivalent or higher qualification, together with experience or proven interest in histo- or neuro-pathology or histology, and two years' (for J.R.F.) or three years' (for S.R.F.) post-graduate research experience.

**SALARY:** Senior Fellowship between £1,745 and £2,155 annually; Junior Fellowship between £1,180 and £1,575 annually. Both are tenable for three years.

Exceptionally, appointment may be as Principal Research Fellow (£2,250 to £3,105). F.S.S.U. terms.

Application forms for the above post and enquiries about opportunities for fellowships elsewhere, to the Civil Service Commission, Savile Row, London W.1, stating age, qualifications, and research interests, quoting S/570.

**MINISTRY OF AGRICULTURE  
FISHERIES AND FOOD****FISHERIES LABORATORY**

Lowestoft

**PHYSICIST or MATHEMATICIAN** (graded S.S.O./S.O.) required in a team concerned with research in physical and chemical oceanography in relation to fisheries. Projects include the study of the changes in the marine environment likely to result from construction or barrages in estuaries, the forecasting of oceanographical conditions on fishing grounds, and the investigation of near bottom currents in relation to fish behaviour. The Laboratory has four research vessels and is able to moor large arrays of oceanographic monitoring equipment.

**QUALIFICATIONS:** 1st or 2nd class honours degree, or equivalent or higher qualification in appropriate subject and, for S.S.O., at least 3 years' post-graduate experience.

**SALARY:** S.O., £926 to £1,574; S.S.O. (minimum age 26) £1,744 to £2,155. Non-contributory pension, promotion prospects.

**APPLICATION FORMS** from the Civil Service Commission, Savile Row, London W.1, quoting S/52-53/MAF. Closing date September 15, 1967. (600)

**UNIVERSITY COLLEGE OF  
NORTH WALES  
BANGOR****SCHOOL OF PLANT BIOLOGY  
RECLAMATION OF METAL  
CONTAMINATED SOILS**

Applications are invited for the post of Research Assistant to investigate the use of plant populations tolerant to toxic metals for the reclamation of toxic mine waste. The work will include the investigation of ecological conditions on metalliferous mine workings and the development of genetic reservoirs of adapted material. A full-time laboratory technician will be available, and there will be support for travel outside the British Isles. Applicants should have a good honours degree and interests in plant ecology, genetics, or mineral nutrition. Salary, £775 to £825 for a period of three years, with superannuation.

Further details can be obtained from the Registrar, to whom applications should be sent, together with the names of two referees, before August 31, 1967. (574)

**UNIVERSITY OF LEEDS: BOTANY DEPARTMENT:** Vacancy for a technician with experience of scientific and technical photography for interesting and varied duties including a considerable load of enlargement printing for light and electron microscopy, reduction printing for lantern slides etc., using high grade modern equipment for which the technician will be responsible. Must be able to work with minimal supervision, though some tuition at the outset could be available. Good working conditions and pension scheme. Salary according to age and experience on University scale for technicians which is constantly under review. Present range £683 to £968.—Applications, giving full professional details and the names of two referees to Professor I. Manton, F.R.S., as soon as possible. (562)

**LABORATORY TECHNICIAN REQUIRED** with experience of electron microscopy, or school leaver with "A" level in related science subject for training in this work.—Applications, stating age, qualifications and names of two referees, to the Administrator, University Laboratory of Physiology, Oxford. (604)

## MICROBIAL BIOCHEMIST

Ranks Hovis McDougall Limited require a microbial biochemist for the fermentation department at their main Research Centre at High Wycombe.

Applicants should have an honours degree in biochemistry, and a Ph.D. would be an advantage. Post-graduate experience in the field of protein synthesis is essential, preferably using micro-fungi. Age 25-35.

This is an important appointment providing the opportunity for really interesting fundamental research in a new and extremely well equipped laboratory. An appropriate salary will be offered and benefits include first-class pension and life assurance arrangements.

Please write with details of age, qualifications, and career to:

The Research Manager,

**RANKS HOVIS McDOUGALL (RESEARCH) LTD.**

Cressex Laboratories,

Lincoln Road, High Wycombe, Bucks.

(609)

### GRASSLAND RESEARCH INSTITUTE HURLEY, MAIDENHEAD, BERKS PLANT SCIENTIST

An officer is required in the Systems Synthesis Section of the Department of Ecology to work on theoretical aspect of plant and crop growth. This will involve the construction and testing of mathematical models of crop growth, mainly grass, and will be linked with similar studies on animal growth and crop utilization to form husbandry systems based on grassland.

Applicants should have a First or Upper Second Class Honours Degree in Botany, Agricultural Botany or Agriculture with at least three years' postgraduate experience. An interest in the syntheses outlined above and experience in plant or crop physiology are essential, while knowledge of the mathematical techniques would be an advantage as would an interest in the application of this work to agricultural practice.

The appointment will be made in the Scientific Officer (£926 to £1,574) or Senior Scientific Officer grade (£1,744 to £2,155) at a point appropriate to qualifications and experience.

Apply, giving curriculum vitae and names of three referees, to Secretary by August 31, 1967. (648)

### COMMONWEALTH AGRICULTURAL BUREAU VACANCY FOR SCIENTIFIC INFORMATION OFFICER

COMMONWEALTH BUREAU OF PLANT  
BREEDING AND GENETICS, CAMBRIDGE

Duties include preparation and editing of abstracts for the journal for *Plant Breeding Abstracts*, classification of biological literature and dealing with scientific inquiries. Applicants preferred with botanical or agricultural degree, or knowledge of or aptitude for foreign languages. Ability to write good English essential. Salary in scale £926 to £2,431, with provision for superannuation. Starting salary according to age, qualifications and experience. Two extra increments after two years' satisfactory service for applicants aged 32 or under on date of appointment.

Application forms and full particulars from Director of the Bureau, School of Agriculture, Cambridge. Closing date October 14. (584)

### ROYAL HOSPITAL FOR SICK CHILDREN EDINBURGH

#### SCIENCE GRADUATE

required to undertake advanced diagnostic techniques in an expanding department, recently rehoused in a new laboratory block. Experience in immunology or biochemistry would be an advantage. Salary in range £963 to £1,658 per annum, depending on qualifications and experience.

Applications, together with the names of two referees, to the Secretary, Edinburgh Central Hospitals, 1 Rillbank Terrace, Edinburgh, 9. (615)

### UNIVERSITY OF EDINBURGH

#### DEPARTMENT OF VETERINARY PATHOLOGY—LECTURER OR ASSISTANT LECTURER

Applications are invited from registered members of the Veterinary Profession for the post of Lecturer or Assistant Lecturer in Veterinary Pathology. The duties will include the teaching of morbid anatomy and histopathology, and there are good facilities for research. Previous experience in pathology will be an advantage but the post offers good training for the recent graduate wishing to study this subject. Salary Scales, Lecturer, £1,470 to £2,630 per annum; Assistant Lecturer, £1,105 to £1,340 per annum, with placement according to qualifications and experience, and with superannuation benefit.

The successful candidate will be expected to take up duty on November 1, 1967, or as soon thereafter as possible.

Further particulars may be obtained from The Secretary to the University, University of Edinburgh, Old College, South Bridge, Edinburgh, with whom applications (six copies), giving the names of two referees, should be lodged not later than September 16, 1967. (644)

### UNIVERSITY OF LIVERPOOL

#### DEPARTMENT OF ANATOMY

Applications are invited for the post of **Lecturer** in the Department of Anatomy. Candidates should hold a medical qualification. The initial salary will be within the range £1,470 to £2,855 per annum, according to qualifications and experience.

Applications, stating age, qualifications and experience, together with the names of three referees, should be received not later than September 16, 1967, by the Registrar, from whom further particulars may be obtained.

Please quote Ref. RV/142/N. (627)

### RESEARCH BIOCHEMIST (B.Sc.) FOR INDUSTRY

A graduate biochemist is required by the Biochemistry Department of Fisons Pest Control Limited for research in pesticide biochemistry. The work consists of studies on the mode of action of pesticides and involves isolation of mitochondria and chloroplasts, with studies of uncoupling of oxidative phosphorylation and inhibition of photosynthesis. Other areas of biochemistry will be investigated in the future. The graduate will initially work under a Ph.D., but the intention is to develop the graduate's capabilities so that he or she can work independently. The post should therefore be suitable for a newly qualified biochemist. The equipment in the department is good, and publication is encouraged. Although a biochemist will be given first preference, biology graduates with a biochemical emphasis will also be considered. It is essential that the applicant has good practical ability with biochemical procedures.

The general conditions of employment and salary are good. There is an excellent contributory pension scheme and an optional medical provident scheme. The Research Station is situated in very pleasant country about 15 miles from Cambridge and four miles from Saffron Walden. Transport is laid on for staff (free of charge) to cover the areas Bishop's Stortford, Saffron Walden, and Cambridge. There is an excellent subsidized canteen and encouragement is given to various sporting and social activities.

Please write, giving brief particulars of qualifications, to

The Personnel Officer (10),  
FISONS PEST CONTROL LIMITED,  
Chesterford Park Research Station,  
near Saffron Walden, Essex.

(622)

### EAST MALLING RESEARCH STATION AND THE DITTON LABORATORY

**Botanist/Plant Physiologist** for studies on the biological changes accompanying maturation and senescence of fruits under selected storage régimes, with particular reference to the physiological disorders arising during long storage and to the application of the results of basic research. A good honours degree, sound experience in physiological and biochemical techniques, and adequate research achievement. Appointment in Senior Scientific Officer grade, subject to qualifications and experience.

Further details and application forms from: The Secretary, East Malling Research Station, Maidstone, Kent. (650)

**SENIOR TECHNICIAN OR TECHNICIAN** required for Microbiology at Queen Mary College (University of London), Mile End Road, E.1. Previous experience is essential and the possession of the I.S.T. or City and Guilds Science Laboratory Technician's Certificate, preferably advanced, or O.N.C. or similar qualification is desirable though not essential. Salary according to age and ability on the scale £912 to £1,150 or £653 to £938 per annum plus London weighting £60 and possible £30 or £80 special qualification award. Five-day week. Four/five weeks annual leave. Pension scheme.—Letters only to Registrar (B/ST), stating full details of age, experience and present work. (558)

## FARADAY DEAD

MAXWELL was right, of course, when he wrote of Faraday (*Nature*, 8, 397; 1873) that "We are probably ignorant even of the name of the science which will be developed out of the materials we are now collecting, when the great philosopher next after Faraday makes his appearance". If Maxwell had been a fortune teller, he would have known that it was Rutherford who would most thoroughly inherit Faraday's reputation. The similarity of the two men is uncanny. Both of them seemed to know by instinct what experiments to do next, although Rutherford was awkward if not clumsy with his hands. Both were extraordinarily economical in that they did not occupy themselves with trivialities or become caught up in pointless complications—Rutherford's string and sealing-wax was not puritanically a virtue but a proof that most of his experiments were designed in eager expectation of the results. Both of them were astonishingly productive (and Faraday's wife was reconciled to his not sleeping well at nights for the excitement of it all). Each of them earned a dubious reputation about mathematics, and it is probably true that Faraday did not understand the calculus which was in fashion when he died a century ago yesterday. Rutherford was not so much ignorant as disdainful, but seems to have been able to convince a whole generation of students at the Cavendish Laboratory that it is as dangerous to let mathematics take charge of physics as to let an army run a government. Both men were in practice marked out from their contemporaries by their power of handling abstractions, and Faraday's feat was if anything the more remarkable. And then they were, the pair of them, quite unashamedly ambitious. Rutherford would put atomic physics on its foundations, while it is clear that Faraday in the autumn of 1831, with his ring induction experiment behind him, saw the whole of electromagnetism at his feet—and a good deal of atomic physics as well.

That said, it is only fair to acknowledge that the centenary of Faraday's death is not the best time to mark his achievements. The officers of the Institution of Electrical Engineers were right when they laid a wreath at Highgate Cemetery in 1831 to mark the centenary of the first demonstration of electromagnetic induction. For the best part of twenty years thereafter, Faraday was in full flood. After that, some kind of anticlimax was almost inevitable, but it is sad that Faraday should so quickly have lost his sparkle in the 1850s. By all accounts his memory, always bad, became fickle and even treacherous. Yet even in his decline Faraday was able to design prophetic experiments. Professor L. Pearce Williams, in his splendid biography of Faraday (Chapman and Hall, 1965), has pointed out that Faraday went looking for what is now the Zeeman effect as late as 1862, when he burnt

a gas flame doped with sodium between the poles of a magnet and looked unsuccessfully for some influence of the magnetic field on the spectral lines. Zeeman, thirty years later, may well have argued that Faraday would not have attempted such an experiment without good reason. Even Faraday's failures were worth knowing of.

This is only one of the proofs that Faraday was not the kind of country bumpkin he is often supposed to have been—good with his hands but dependent on the Maxwells of his time for support and in particular for mathematics. If anything, the boot was on the other foot. Faraday was the one who formulated—in words—the concept of a field of force; the manipulators of differential equations were so successful in the second half of the nineteenth century that physics was unreasonably saddled with the doctrine of the all-pervading imponderable ether, elastic constants and all. Maxwell himself is entirely explicit about his debt to Faraday, and says quite honestly in the introduction to his classic translation of the doctrine of tubes of force into mathematics that Faraday had already done the physics. But how could somebody who learned his science by apprenticeship, and from Humphry Davy at that, be so capable of abstraction? Genius apart, there is probably something in the view that the informality of his education was more a help than a hindrance at a time when it was above all necessary to find some new conceptual framework within which to accommodate the phenomena of electricity and magnetism and of their interaction with matter. Faraday was more free than his rivals, Ampère and Oersted among them, to admit that lines of force could sometimes be wrapped around in circles. Indeed, much earlier in his career, he had shown hankerings after the doctrine of Bosovich that atoms are not like billiard balls at all, but are more like abstract mathematical points with fields of force attached. It is tempting to ask where Faraday would have been led by a full-blooded devotion to that cause, but that is asking for too much.

The truth is that Faraday's interests, like those of his contemporaries, were curiously prophetic. Looking back, it now seems clear that the roots of the upheaval initiated in the nineties by Lorentz on the mainland of Europe and Thomson in Britain lay in the fifties and sixties, when Faraday's working life was nearly over. He himself tinkered with electrical discharges in gases, which was a fashionable thing to do, but nobody could then make a vacuum good enough to anticipate Thomson's measurement of  $e/m$ . Faraday's laws of electrolysis, linking a specific quantity of electricity with specific quantities of material, could well have been more suggestive of atomic theories than they were. The interaction between light and matter was a common preoccupation, and if it had not been

for the red herring of the ether doctrine, it is hard to believe it would have been necessary to wait for Kramers to put dispersion theory on a solid foundation. In the event, Maxwell's equations showing explicitly the conjugate relationship between electricity and magnetism made further progress possible—at least when they had become familiar. In other words, there is no gulf worth speaking of between Faraday and the modern world. Even the name of field theory has become a science of its own. Given that there have been 100 years, that is a remarkable tribute.

## MODEST CLAIRVOYANCE

THE National Science Foundation has embarked on an interesting and possibly important experiment by setting out to forecast future expenditure on research and development in the United States (*National Patterns of R and D Resources*, NSF 67-7, Government Printing Office, \$0.30). Much of the forecast is based on the figures supplied by federal agencies or is derived from estimates obtained by surveys carried out in industry and the universities. The figures are based on 1965 prices, and the forecast makes the assumption that there will be no drastic change in the economic climate. Although the forecasting consists of little more than intelligent extrapolation, and although the foundation—to begin with, at least—has modestly confined itself to a forecast for 1967 (already half gone) and 1968, anything that smacks of being an objective but realistic forecast of the immediate future could prove to be immensely valuable in the management of scientific resources.

So far as it goes, the forecast for 1968 is reasonably cheerful, given the talk there has been in the past few years about the declining rate of growth for expenditure on research and development and the pressure there has been on the American economy for the past year. Vietnam casts a long shadow. In aggregate, the NSF expects that the United States will spend a total of \$23,800 million on research and development in 1967 and \$25,000 million in 1968—a comparatively modest increase of 5 per cent, or rather less than the 6.9 per cent which is likely to represent the average compound rate of growth between 1965 and 1968. But by now, of course, nobody expects that spending on research and development could continue to double every five years as it did between 1953 and 1958. In reality, total expenditure has increased by a smaller percentage each year since the beginning of the sixties, although it is still moving ahead more quickly than the GNP. Even at this rate, research and development in the United States should reach 5 per cent of the GNP—it is roughly 3 per cent now—long before 1990.

The outlook for basic research is more obscure. The NSF has found it easier to produce a forecast for entire expenditure on research and development in 1968 than to say just what proportion of the total the several agencies involved, in industry as well as the Federal Government, will choose to devote to basic work. It

has been plain for some time that the unprecedented growth rate in the early sixties for expenditure on basic research, which worked out at an average of 17.0 per cent between 1958 and 1965, had fallen to 10.5 per cent in 1965-66. There is nothing in the US budget for the fiscal year which has just begun to suggest a return to the days of plenty. Indeed, the continuing pressure on government expenditure, of which the 10 per cent income tax surcharge is only one symptom, is a real cause for anxiety now that the Government's contribution to basic research has risen to two-thirds of the total. A little parsimony in Congress could do a lot of damage. Yet the NSF forecast takes a comparatively cheerful view of what the Federal Government will do for the universities in the years immediately ahead. If the figures are to be taken seriously, Washington will contribute \$1,600 million to the cost of university research and development in 1968, which implies that the government's contribution will have doubled in rather less than six years and that it will amount, in 1968, to 61 per cent of all that is spent in the universities. It is to be hoped that this cheerfulness will be justified by events. The next few months will be critical, if only because preparations for the budget for the year beginning in July 1968 will have to be made in an unusually sombre atmosphere. The universities will be lucky if they get the extra 10 per cent of federal money which the NSF predicts. The trouble is that they probably need a good deal more than that if the growth of the universities is not to be checked.

The forecast may, however, be more significant than the numbers suggest. For one thing, forecasts are the essential starting point for what is often called indicative planning. In practice this means that it should be possible to make comparisons of, say, the future scale of expenditure on research and development and the future supply of trained manpower in such a way as to decide whether skilled people will be easier or more difficult to find in the years ahead. This could be important if the Federal Government were for some reason to find itself embarking on a huge new programme of research and development, but industrialists may also find the forecasts useful in similar ways. And if the forecasts stretched three or four years ahead, of course, it would be possible for universities to trim their policies—and for students to adjust their choices of courses to follow—so as to win the greatest advantage from circumstances as they develop. Indeed, the benefits which might be derived from these and other comparisons are potentially so great that everybody will now no doubt be hoping that the NSF will soon summon up the courage to take a somewhat longer look into the immediate future. Nobody expects fortune telling, and there are legitimate doubts of the significance of forecasts which rely, as forecasts must, on hazy evidence such as the guesses by businessmen about the scale of involvement in research and development some years ahead, when economic circumstances may be quite transformed. Thus forecasts may be less an indication of future

reality than of present misconceptions. But any forecasts are better than none, especially if their limitations are openly acknowledged. Probably the NSF will want to stick to comparatively modest forecasting until it has won a reputation for clairvoyance, but too much caution would be a mistake. Ironically, the evident value of this beginning will without question set off a clamour for a three or even a five year forecast as well.

There remains the question of how the forecasts can influence the willingness of the Federal Government to spend money on research and development. (Possibly, it is worth recalling that there are limits to the extent to which an agency like the NSF, itself dependent on the Government for funds, can forecast how much its own benefactor will be prepared to spend on agencies like itself.) Pressures may spring up in all directions, and the greatest danger is that Congress and the others holding purse strings may be mesmerized by the figures which have been produced for the various rates of growth. Experience in Britain as well as in the United States shows that treasuries find it almost irresistible to argue that the rates of growth for expenditure on science ought to be linked somehow to the rate of growth of the GNP or to the change of some other economic indicator. This is like putting the cart before the horse. Too much respect for the GNP as a universal yardstick is one way of bringing growth to a halt. In an expanding economy, it is inevitable that some things should grow more quickly than others, and it would be a great surprise if research and development were not among the most vigorous consumers of extra funds. If Congress wants to use the forecasts now produced as a guide to action in the next year or so, it should start from the forecasts of the skilled manpower that will be available in the year ahead and then reckon that enough money must be allocated for these people to be efficiently employed.

## WHERE ARE THE QUASARS?

THE most distinctive property of the quasars is that the radiation from them is shifted enormously to the red, and any attempt to account for their existence must begin with that. But does the red-shift imply recession? And is an apparent recession of the quasars to be interpreted as participation in the general expansion of the universe? This is the train of thought which led, immediately after the discovery of the first of these objects, to the supposition that quasars are for one thing extremely far away, and therefore exceedingly powerful sources of radiation even by the yardsticks of astrophysics. But if red-shift implies distance, and if quasars are distributed more or less randomly throughout the universe, there should be a relationship between brightness and red-shift. The quasars with the biggest red-shifts should, on the average, be the faintest. That is how the argument

began, but the problem of the quasars has so far been enormously complicated and confused by the failure to pick out anything like a significant correlation between the brightness of quasars and the red-shift of their radiation. A year ago, with an air of resignation, Hoyle and Burbidge wrote that "as new red-shift values become increasingly available, the plot of the observed quasi-stellar objects has assumed more and more the aspects of a scatter diagram" (*Nature*, **210**, 1346; 1966). Although there have been several attempts to explain how a real correlation between brightness and red-shift may be obscured by irrelevancies, the absence of a correlation has been the chief reason why people have been energetically seeking ways of accounting for quasars which do not entail rapid recession at the edges of the universe.

It is too soon to know whether the problem will be simplified by the two articles on the red-shift relationship which appear on pages 917 and 919. Now that more data have accumulated, the beginnings of what seems to be a real correlation between brightness and red-shift does seem to be emerging. Horton and Daintree, writing from Jodrell Bank, argue that the relationship is more clearly apparent at higher radio frequencies than those used in earlier comparisons, and they claim that the most compact and the brightest of the quasars in their sample have a brightness and red-shift related by a simple curve not altogether different from the predictions of some cosmological models. In their view, the failure of all quasars to lie on the same smooth curve may be accounted for by processes such as internal absorption of radiation within particular objects. To them, red-shift implies great distance.

Although Longair and Scheuer agree that the newly accumulated data on quasars imply a significant relationship between red-shift and brightness, their interpretation is quite different. They argue that the observed brightness of a quasar with a pronounced red-shift is not itself a measure of the power emitted, but must be corrected to account for several complicating factors—the fact that a red-shift of any origin will reduce the energy of photons and the rate at which they reach an observer, for example. In other words, to them a faintly significant correlation between red-shift and brightness is not a sign that quasars are distant objects but rather a somewhat unsurprising happening which is entirely consistent with the view that the red-shift of quasars has nothing to do with rapid recession or great distance. The most convincing part of what Longair and Scheuer have to say is based on an analysis of the optical brightness of a number of quasars. The difficulty, of course, is that their negative conclusion may not be valid for the data corresponding to the very high radio frequencies at which Horton and Daintree claim the relationship is most apparent. In other words, the two arguments are not necessarily in conflict. The immediate result, no doubt, will be a careful poring over data. The theoreticians anxious to get on with model building will have to wait a little longer.

## NEWS AND VIEWS

### Plans for Kensington

THE small area of London bounded by Kensington Gore, Cromwell Road and Queens Gate contains some of the most important museums and institutions in Britain. The Science, Natural History and Victoria and Albert Museums, Imperial College, the Royal Colleges of Art and Music and the Royal Albert Hall, are all situated there. But this very concentration of collections and colleges, which makes this part of Kensington one of the most important cultural and educational areas in London, is proving disadvantageous. An important event at the Albert Hall, for example, "turns the whole area into a seething mass of motor vehicles", in the words of a letter to the *Times* by the directors of the institutions. They then announced that they have formed themselves into a standing committee to represent to the authorities the unique character of the district and to see that this is taken into account in the planning of buildings and roads.

The institutions have, for example, failed in their separate attempts to have traffic conditions improved. Those students of Imperial College living across Exhibition Road from the main buildings have a great deal of difficulty crossing over the road to work in the mornings. Then, ice-cream vans accumulate outside the Science Museum, causing the pavements to be littered with ice-cream cartons and sticks. The derisory fines that are imposed on the owners of the vans have not stopped them from coming.

When the committee has dealt with the more immediate problems, it intends to "promote a study of the problems and potentialities of the area", in particular to see what might be done to turn the area into an educational and cultural precinct. Since 1959, the University of London has been trying to turn the Bloomsbury area into such a precinct by buying houses in the region as their leases expire and by establishing university offices and departments in them. The original plan of this venture included proposals that certain streets should be closed to traffic, but this has not yet happened.

### Cheerful Association

THE British Association, which is due to begin its annual meeting at Leeds on August 31, has unexpectedly been able to show a small surplus on its accounts for the years 1966-67. On the heels of a deficit of £7,000-odd for the previous year and a gloomy forecast from the general treasurer, this seems a proud achievement. In reality, however, the association is more despondent than delighted, for its balanced budget is more the result of curtailed expenditure than increased income. The Department of Education and Science remains deaf to the plea that the grant of £12,500 which the department has made in recent years for the support of the lecture service should be doubled for a start, and that the department should also match private contributions towards the cost of these social services

up to a maximum of £12,500. The general treasurer does not in this year's annual report repeat his explicit complaints against the department, but he does mention with approval the way in which the Ministry of Technology has decided to make a further grant of £10,000 towards the cost of the propaganda which the association is doing among young people in the cause of the more fruitful application of science. According to the general treasurer, the need for economy has also led to potentially profitable innovations, such as the decision that the association's journal *The Advancement of Science* should from April 1967 be published on a commercial basis.

The chief consequence of straitened circumstances has been a reduction of the extent to which area branches of the British Association have been able to provide lectures on scientific subjects for local organizations. The total number of regionally organized lectures fell from 1,409 in 1965-66 to 998, but the central service provided by the headquarters of the British Association remained more or less unchanged at 311. One striking feature of the comparison between the two years is the decline in the proportion of adults attending lectures provided by the association. Evidently the Women's Institutes have been more seriously deprived of lectures on science than have the schools. There is, of course, nothing in the report to indicate whether the slackening of support from the British Association has been accompanied by an increase of support—not necessarily financial—from other sources. Whatever may have happened, there is obvious comfort to be drawn from the way in which the science fairs, which began as a kind of juvenile sideshow at the annual meetings, have become a continuing hit, first with the *Sunday Times* and now with BBC Television. The association is also modestly pleased about its work with audio-visual aids for education and with attempts to introduce more science lectures to colleges of education, although it is not equally successful everywhere. As it diversifies, the association may have to acknowledge occasional failures.

### Clean Air at Harwell

IN a report issued this week, the National Society for Clean Air urges the Ministry of Transport to fix limits for the contents of car and lorry exhausts. The report, "Air Pollution from Road Vehicles", states that although road and rail transport together use only one-tenth of the fuel consumed in Britain at present, car exhaust pollution so affects city streets that conditions in them could become intolerable as the number of cars increases, if no controls are introduced. Britain will be spared the photochemical smog that afflicts Los Angeles, unless, ironically enough, the skies become clearer. Even then, the most harmful product of the motor car will continue to be carbon monoxide. Already the concentration of this gas in streets can reach dangerous levels—as much as 360 parts per million was recorded in Oxford Circus. It is forbidden to expose industrial workers to a concentration of more than 100 p.p.m. in an eight hour day.

The best methods of reducing pollution, the report concludes, are by installing modified carburettors and fuel injection systems; exhaust after-burners and catalysts are less effective. The report criticizes the

forthcoming British Standards Specification on the level of smoke from diesel engines. Apparently, most existing engines produce smoke at a rate well below that specified, so that the standard is unlikely to prove much use in reducing pollution in the future.

The society has not been the only body with the subject on its mind this week. In a joint statement with the United Kingdom Atomic Energy Authority, the Ministry of Technology announces that scientists at Harwell are to co-operate with their research staff at Warren Spring Laboratory, to investigate problems in "health physics" and the physical chemistry of pollutants.

Of necessity, Harwell has been concerned for some time with radioactive pollution of the atmosphere, and research teams involved in this work have acquired considerable experience of measurement of the properties of aerosols, estimation of maximum allowable concentrations, and other work common to the study of both radioactive and industrial pollutants. At the same time, it is expected that the application to the study of pollution of techniques developed at Harwell will elucidate the life cycles of pollutants, their deposition on various surfaces, and the effect of them on rain.

Last November, the Chairman of the Congressional Joint Committee on Atomic Energy suggested that the United States Atomic Energy Commission should undertake pollution research. Nothing has come of this so far, but it is certain that any American effort would far outweigh that being made in Britain—the Harwell team will never have more than twelve workers. So it is perhaps a little disappointing that no research is to be undertaken into the ecological effects of pollution in Britain, which would not, of course, be covered by an American programme. No one can doubt the need for ecological research of this kind, in which radio tracers might be of great use. According to the National Society for Clean Air, photochemical smog greatly harms plants in America, and in Britain "it is a matter of common experience that some damage to roadside vegetation is caused by motor vehicle emissions".

## Clubs for Colloquia

MECHANICAL engineers in Europe, with help as well as encouragement from the Royal Society, have formed an organization to organize informal specialized conferences on theoretical and applied mechanics. Under the title of EUROMECH, the plan is to organize several conferences each year in various European centres. In future there will be a strict observance of the rule that no more than fifty people shall attend any one conference, although much will depend on the toughness of the chairman appointed to take charge of each of them.

The origins of this scheme lie in the International Congress of Applied Mechanics at Munich in 1964, when a number of the participants set out to organize smaller meetings at which specific subjects could be discussed. By this time a group of chemists had formed an organization with similar purposes under the banner of EUCHEM, chiefly under the prodding of Professor H. W. Thompson, foreign secretary of the Royal Society, so that the mechanical engineers had a useful precedent to follow, and the Royal Society

offered to provide secretarial services for both of them. The new development is that the EUROMECH has now been formed as a permanent organization, with a committee of four (elected from the member countries in rotation) under Professor G. K. Batchelor (Cambridge) and Dr. D. Küchemann of the Royal Aircraft Establishment as secretary.

In the immediate future, EUROMECH plans four conferences on the mechanics of liquids containing bubbles (Grenoble, April 23, 1968), thermoelasticity (Jablonna, October 2, 1967), aerodynamics of rarefied gas flows (Paris, February 7, 1968) and aerodynamics of flows with large velocity fluctuations (Prague, March 27, 1968). Apparently the organization is hoping to run its conferences on a self-financing basis, with participants usually paying their own expenses. Whether this self-denying ordinance will always enable all desirable participants to attend will presumably become clear as experience accumulates. Apparently the Council of Europe has already provided some modest help in this direction, and it is always possible that national academies may be able to provide some help from the funds which they are now accumulating in the cause of European collaboration. Another question outstanding is the extent to which the EUROMECH and EUCHEM will serve as precedents for attempts in other fields to provide some vehicle for communication smaller than a full-blown conference but bigger than a personal visit.

## Species in Stock

LAST week saw the publication of a useful little booklet, a revised "Directory of Collections and List of Species maintained in Canada 1967" (HMSO). This directory is one of a series published on behalf of the Permanent Committee of Commonwealth Collections of Micro-organisms. The organization, established in 1957 with headquarters in London, is under the auspices of the Commonwealth Science Committee and provides for the co-ordination and exchange of information on maintaining cultures between the member nations: Australia, New Zealand, Canada, India, Ghana, Trinidad, the United Kingdom and lately Jamaica. It fosters the maintenance and expansion of cultures. Recently, for example, it provided funds to maintain a collection in Jamaica that would otherwise have been lost, and it tries, by way of the directories, to make the cultures accessible to anyone who needs them.

The directories of all the member nations, last published in 1960, are being revised during the next two years and the new Australian directory has already appeared (HMSO, June 1967). The information for the directories is collected by national committees which keep an eye on all the collections maintained and endeavour to make them as complete as possible. It is surprising therefore to find that the only species of algae listed in the Canadian directory is *Chlerella vulgaris*. Is there really no culture of *Chlamydomonas* anywhere in Canada?

## Grass Technology

BRITAIN has never really understood that plant breeding is a technology—this at least is the opinion expressed by Mr N. W. Simmonds, director of the Scottish Plant Breeding Station, in the station's annual

report for 1966-67. He says that the results have been small scale of operation, swamping by foreign varieties in several crops, the absence, or near absence, of serious commercial effort, and consequently, poor service to the British farmer. Mr Simmonds says that much good science has been done in Britain, for example, on genetic studies, but it is likely that the continental or American breeders will profit from the research, and Britain will find itself paying royalties on the products of its own inventions. If these fundamental studies are to be put to use, a sustained and applied effort will be required.

In his view, the passing of the Seeds Act (1964) was a crucial event followed by the introduction under the act of schemes relating to the various crops. The act makes it possible for breeders to levy royalties on their own varieties in commercial cultivation and should stimulate commercial plant breeding in Britain. If this fails, then there would have to be a great expansion of state breeding. If the act does succeed, Mr Simmonds thinks that the official breeding stations will be pressed in two directions—partly towards fundamental studies and partly towards breeding crops which are not commercially attractive to the breeders. Mr Simmonds thinks the suggestion that the fundamental studies should be adapted to the universities is wrong in that the studies demand facilities such as land, glasshouses and assistants which could rarely be achieved by British universities, and the studies are basically economic in orientation and would therefore be regarded as "impure" in university circles.

## More Accidents

THE number of accidents in British factories and at building sites rose again last year, according to the Annual Report of the Chief Inspector of Factories (HMSO, 12s. 6d.). The increase was less than over the previous two years, but the fact that almost 300,000 people were injured and that fatal accidents increased from 627 to 701 can be pleasing to no one. The number of workers under eighteen involved in accidents did, however, fall slightly, from 18,200 to 17,400.

The Chief Inspector, Mr R. K. Christy, emphasizing the need for safety consciousness in industry, said that every establishment should have a trained safety officer, and that managers should plan for safety just as they plan their production or research and development. More specific recommendations are contained in a chapter concerned with the electrical industry in which, however, the accident rate of 25.9 per 1,000 workers is comparatively low. A new testing service is to be set up by the Ministry of Technology to certify the safety of electrical equipment used in flammable atmospheres.

Some interesting comparisons can be made between accident rates in various types of industry. Working in a jute factory, for example, appears to be dangerous: 61 workers in every thousand were involved in an accident last year, twice as high a rate as that in the cotton spinning industry, and nine times as high as that in the manufacture of stockings and knitwear. Or again, there were ten accidents per thousand workers in office machine factories, but the rate was thirty-five among those working on electrical domestic appliances. How can it be so much safer to make a typewriter than an iron, a duplicator than a washing machine? And an inherently dangerous occupation like the manu-

facture of explosives is, in fact, roughly four times as safe as working in a brickworks. Even more mysterious is the incidence of accidents in certain regions. In the Sheffield area, 63 in every thousand workers are injured; the figures for Birmingham and Nottingham are 25 and 28. The inspectorate cannot explain this, and comes to the conclusion that "numbers of reported accidents by themselves are not a reliable guide to accident prevention performance". It would be interesting to know if large establishments give more consideration to safety than small ones, and if the large number of accidents in the building industry (45,600, of which 288 were fatal) is due as much to this cause as to the nature of the work.

The report also discusses the difficulty of classifying and enumerating accidents. At present an accident is described as an injury that disables a person from working for three days. It is the duty of the employer to inform the inspectorate on the fourth day after the injury, but the extent of the injury may not then be clear. A system of classification based on the hours of work lost will not distinguish between restricted, but permanent, injuries, such as the loss of a finger, and general, but temporary, injuries, such as a badly sprained back. More than three-quarters of all the accidents that happened resulted in cuts, abrasions and strains. It is difficult to say how serious these injuries were, or how easily they could have been avoided.

The report does give details of the causes of fatal accidents. Of the 372 fatal accidents in industry, 95 involved a clear breach of the law by the occupier of the factory, and only 6 by the worker himself. In building, of the 288 deaths, 160 were caused by the employers breaking the law, 22 by the worker. The introduction of highly technical processes and sophisticated plant seems to be an unimportant factor in the increase in the number of accidents. "There is little evidence to suggest that industry is inadequately equipped to deal with the hazards that technological changes may involve; there is, however, abundant evidence to show that in some factories the most obvious dangers continued to be ignored."

## The Sutton Hoo Ship

THE British Museum has reopened the excavation of the Sutton Hoo ship and in the next decade hopes also to open the twelve remaining royal graves at the site on the banks of the Deben in Suffolk. When the museum began preparing a four volume definitive description of the Sutton Hoo burial ship so many questions arose that it decided to re-excavate the site.

The original discovery of the ship and its priceless treasures was made in 1939 and with the greatest generosity the landowner Mrs Edith Pretty gave the treasure to the nation; it is now in the British Museum. Mrs Pretty initiated the first excavation and when the complexity of the mound and richness of the treasure were realized Mr Charles Phillips, a Cambridge archaeologist, was invited to take over the excavation and handle the emergency. Considering the imminence of the Second World War and the lack in Britain of any archaeologist with experience of such a rich and complex site, the operation was remarkably successful. Unfortunately, however, at the end of the dig the site was, with lack of foresight, written off as of no further value. No effort was made to cover the ship, which was filled

with bracken to the gunwales and left two years exposed to frost and silting. It was to suffer much worse. By some lamentable failure of communications, the site was not scheduled as an ancient monument and, with Mrs Pretty dead, the land was taken over by the War Office as a battle training ground. It suffered accordingly.

When the British Museum team arrived this summer under the direction of Dr R. L. S. Bruce-Mitford of the Museum and Mr P. Ashbee, there was no trace of the ship. It was under five feet of silt with a machine gun emplacement dug through the stern and an unexploded bomb alongside which the Royal Engineers had to deal with.

Exactly why are the British Museum re-excavating the site? There are several reasons, all stemming from the fact that the original dig was such a hurried affair. Most importantly, complete details of the ship's construction were not recorded and these are of major importance. It is not every day that there is an opportunity of learning how a seventh century ship was built and this ship was no mere cenotaph—it was old and repaired and must have seen considerable service. The museum also wanted to look under the side of the ship for traces of the missing forty oars and steering paddle, to find the dimensions of the mound which had not been recorded and to sift through the mound of debris from the previous excavation looking for small fragments missing from the pieces of treasure.

The hunt has met with some success. Although all that was under the ship was two split logs supporting it, with no traces of the oars, the museum has found in the debris missing fragments from the treasure, notably the third of the boat's head decorations from the largest of the three hanging bowls and parts of the helmet and shield. These fragments are to be restored at the museum. A complete plaster cast of the hull has been made with great skill, and a fibre-glass positive will be taken from this. All that prevents the museum from making a full scale sailing replica of the ship is lack of money. It would cost £20,000.

There has always been a mystery about who, if anyone, was buried in this ship. Was it a grave or a cenotaph? Numismatists disagree over the dating of the thirty-seven gold coins in the ship's treasure, so it is not known who was reigning about the time of the burial and no skeleton was found in 1939. Mr H. Barker of the British Museum Laboratory is trying to determine if a body was ever in the burial by analysing the 2,000 iron rivets and samples of adjacent soil for deposits of iron phosphate.

In 1950 Mr Barker reported (*Nature*, **166**, 348; 1950) that the only fragment of material originally excavated in 1939 and then thought to be bone was, in fact, amorphous ferric phosphate. It did, however, contain carbon particles distributed as in calcined bone. Since the soil at Sutton Hoo is acid, the subsoil sand has a pH of 4.5, and would decompose bone. Mr Barker suggests that phosphate liberated from bone reacts with any iron to produce ferric phosphate. This summer the position of the 2,000 or so rivets in the ship has been mapped and each will be analysed for deposits of ferric phosphate. Even though many of the rivets were displaced by the tanks that rolled over the ship in the 1940s, it is hoped that the pattern of distribution of any ferric phosphate may give a clue as to whether or not a body was buried with the ship.

## Crystal Chemistry of Proteins

from our Molecular Biology Correspondent

THE pursuit of three dimensional protein structures by X-ray analysis has given rise to a number of highly profitable by-products. Among these is the discovery, chiefly associated with F. M. Richards and his co-workers, that protein chemistry can be made to go on in the crystalline state and that X-ray diffraction can be applied dynamically to its observation. Richards and his associates have explored the diffusion of various reagents into ribonuclease and carboxypeptidase crystals, and have shown, for example, that substrates can be turned over in the crystal, unreacted substrate diffusing in and the reaction products out. By the introduction of a bifunctional reagent, intermolecular cross-links can be formed, so that an insoluble, but still enzymically active, crystal results.

The latest article (Wyckoff *et al.*, *J. Mol. Biol.*, **27**, 563; 1967) describes elegant techniques for observing physical and chemical processes in protein crystals, gives a number of applications to the study of ribonuclease-S (pancreatic ribonuclease in which a peptide bond has been cleaved by exposure to subtilisin), and indicates how the methods have helped in the determination of the structure to 3Å resolution.

The method involves mounting the protein crystal (less than 1 mm in size) in a flow cell, which is placed in a diffractometer. Any suitable reflexion can then be selected for observation, and its intensity monitored as a function of time while an appropriate reagent is allowed to diffuse into the crystal. Rate curves are given for diffusion of ammonium sulphate and of inhibitors through the crystal. Dilution of the ammonium sulphate mother liquor leads to an intensity diminution in a half-time of 90 seconds. By contrast the diffusion of an inhibitor (an iodouridine phosphate) involves a half-time of 11 hours and the process is still measurably incomplete after three days. This enormous difference in the rates of penetration of small species is not explicable simply in terms of their diffusion coefficients, which differ only by a factor of about two: on the one hand the crystal lattice probably operates as a molecular sieve, impeding the progress of the larger nucleotide molecule; on the other, the binding of the inhibitor to the protein leads to a retardation (as in adsorption chromatography). A similar effect—titration of ionizing groups—is evidently responsible for the slowness of the response to a change in pH outside the crystal; in this case a change in the unit-cell dimensions is observed. The same system has been used to obtain binding curves for various inhibitors, to determine the number of sites—for the iodouridine phosphate, for example, a secondary binding site is surmised to exist—and to ascertain whether different ligands compete for the same site.

Since ligands can be washed out of a crystal with fresh ammonium sulphate solution, it has been possible to use a single crystal without disturbing its mounting in the goniometer for the comparison of a series of heavy-atom derivatives and the like. A single crystal was used in the same way for the collection of reflexions in the presence and absence of the isomorphous substituent, so that small intensity changes could be recognized with a high degree of confidence. The end-product of this work—the structure in detail of the enzyme-inhibitor complex—is promised soon.

## How Colchicine Works

by our Cell Biology Correspondent

ANY attempt to explain how colchicine functions must account for all the diverse and seemingly unrelated effects it has on cells. For example, apart from its well known ability to block mitosis by interfering with the structure of the mitotic spindle, colchicine reversibly induces the retraction of the axopods of protozoa, disrupts myofibril morphogenesis, interferes with the deposition of cellulose fibres in plant cell walls, causes acute poisoning in mammals primarily by its toxicity to the central nervous system and, most surprising of all, relieves the pain of gout.

The important discovery, made by Borisky and Taylor (*J. Cell Biol.*, **34**, 525 and 535; 1967), that colchicine binds specifically and reversibly to a sub-unit protein of microtubules has led them to propose that colchicine acts by preventing the formation of microtubules—a hypothesis which provides plausible explanations of all the diverse effects of colchicine.

What Borisky and Taylor have found is that tritiated colchicine administered to HeLa and KB cells can be recovered, after homogenization of the cells, in a soluble fraction in which the colchicine is specifically and non-covalently bound to a protein with a sedimentation coefficient of 6S. A similar reversible binding, with the same equilibrium constant and kinetics, takes place *in vitro* when the soluble extract from the cells, both at interphase and in mitosis, is incubated with the colchicine. Furthermore, the colchicine is not chemically modified when it forms the complex.

The problem then becomes one of identifying the source of 6S protein, the target site of colchicine. Two pieces of evidence show it to be a sub-unit protein of microtubules. First, a survey of the colchicine binding activity of several cell types and isolated organelles has revealed a strong positive correlation between the amount of colchicine bound and the abundance of microtubules. Mitotic cells, tritiated and flagellated cells, sperm and nerve cells all bind large amounts of colchicine and the only structures known to be common to these cells are microtubules. Slime moulds, on the other hand, have few if any microtubules and bind very little colchicine. It is interesting that, although recent evidence (see *Nature*, **215**, 345; 1967) suggests not all microtubules are identical, they all seem to share the property of strongly binding colchicine.

Second, when isolated sea urchin mitotic apparatus is extracted at low ionic strengths, the microtubules disappear and the soluble extract contains the 6S colchicine-binding protein. Borisky and Taylor conclude that the 6S material is a constituent of the microtubules, and Shelanski and Taylor (*J. Cell Biol.*, **34**, 549; 1967) present other evidence that the microtubules of sea urchin sperm tails also contain this 6S protein.

Thus Borisky and Taylor propose that colchicine acts by binding to sub-unit protein of the microtubules and preventing its polymerization into microtubules. They envisage that this polymerization is an equilibrium process, possibly nucleated by centrioles, and the equilibrium can be shifted in favour of the monomer by complexing monomers with colchicine. They are apparently in the process of testing this hypothesis directly by an *in vitro* experiment.

All the known effects of colchicine can be plausibly explained in terms of the hypothesis—even its toxicity to the central nervous system and its relief of gout pains. Nerve cells contain microtubules and doubtless their depolymerization would have deleterious effects. It would be of great interest to know whether neurofilament protein, as well as neurotubule protein, binds colchicine because a possible relationship between the two structures has been the source of much speculation. In gout, the colchicine may well give relief to the pain by disrupting the microtubules in leucocytes, thereby inhibiting phagocytosis and relieving the inflammation that accompanies it.

## Soft Rot Enzymology

by our Microbiology Correspondent

A WELL known response of plants to microbial infection is an increase of phenol oxidase activity followed by the deposition of dark oxidation products. Phenols and their derived pigments usually suppress the growth of phytopathogens *in situ* and limit the area of diseased tissue. In turn, certain phytopathogens are able to counter such host defence mechanisms. The factors which determine plant resistance or microbial virulence are extremely complex and, although many attempts have been made to correlate the disease condition with microbial activities, understanding in this area remains fragmentary.

The activities of phenol oxidase, pectinase and dehydrogenases during the progress of potato soft rot have been reported recently by Lovrekovich, Lovrekovich and Stahmann (*Phytopathology*, **57**, 737; 1967). High concentrations of the causative bacterium *Erwinia carotovora* were inoculated into healthy tubers and after 24 hours the infection locus was surrounded by a large zone of white rotted tissue. This latter zone was bounded by a narrow black margin which delimited the spread of the pathogen. Disease development was very rapid for the first day, but thereafter the rotting was contained by the host. Phenol oxidation in the rotted area was clearly inhibited by the bacteria because phenol oxidase and potential substrates were present. Furthermore, when bacteria were added to pigmented potato sap, the melanoid colour was lost. The bacterial inhibition of phenol oxidation was studied in model systems containing various preparations of the enzyme and catechol as the substrate. The bacteria were able to inhibit the oxidation only when glucose was supplied to the reaction mixture, a result suggesting that the sugar acted as a source of reducing power in the inhibition. Rotted tubers possessed very high levels of dehydrogenase activity in comparison to healthy tubers, and this activity was associated with the bacteria rather than with the host tissues. The authors conclude that the white rot can be explained in terms of the action of cell bound bacterial dehydrogenases maintaining the potato phenols in a reduced state even in the presence of active phenol oxidase. How then is the spread of the rot confined?

The black infection margin comprises macerated tissue, and Stahmann and his colleagues showed that extracellular bacterial pectinase was responsible for this development. Evidently at sites removed from the pathogen, activity of the host phenol oxidase is

unimpaired and it is reasonable to postulate that the black ring constitutes a host defence mechanism. Indeed, tubers pretreated with pectinase had much increased resistance to subsequent soft rot infection. The authors suggest that the pectic enzymes that diffuse into the potato tissues induce the phenol oxidase. The actual "induction" process is not discussed, but it is unlikely to involve *de novo* synthesis of the oxidase because healthy tissues are abundantly supplied with this enzyme. Rather, the process may be one of oxidase release or activation, phenomena known to occur under a variety of abnormal conditions in lower and higher organisms.

Significant as these findings are, they comprise only some of the factors affecting disease resistance and virulence. For example, below the white rotted tissue, black ring formation cannot be detected but the pathogen is restricted in its spread none the less. Here the decisive factor is the supply of oxygen and, when it becomes limiting, both the growth of the pathogen and the oxidation of the phenolics are repressed. The dehydrogenase activity of *E. carotovora* is, however, an important factor in its virulence and, in a wider context, the higher reducing capacity of diseased tissues is characteristic of fungal as well as bacterial host-parasite interactions.

## A Possible Relationship between Radio Flux Density and Red-shift for Quasars

by

P. W. HORTON

E. J. DAINTREE

Nuffield Radio Astronomy Laboratories,  
University of Manchester

Demonstration of a relationship between the flux densities and red-shifts of quasars suggests that the red-shifts give an indication of their distances.

ASSUMING the red-shifts of quasars to be an indication of their distances, it might be expected that there would be a relation between their flux densities and red-shifts. Hoyle and Burbidge<sup>1</sup> found no such relation in the available experimental data from the revised 3C survey at 178 Mc/s. Bolton<sup>2</sup> suggested that this relation was obscured by a large dispersion in intrinsic luminosities, and Longair<sup>3</sup> pointed out that the relationship would be further modified by any cosmological evolution in the intrinsic luminosity. It now appears possible to demonstrate this relationship experimentally, partly because further data are available but more particularly because we are using flux densities at high frequencies. We compare the results for emitted frequencies of 500 Mc/s and 5,000 Mc/s, obtaining the flux densities at the relevant frequencies by interpolation from the observed spectra. New observations at 2,695 Mc/s and 4,995 Mc/s (Horton, Conway and Daintree, in preparation) were used to extend the spectra of quasars in the 3C catalogue. The spectra of more quasars were taken from the Parkes surveys<sup>4,5</sup> and red-shift data from refs. 6 and 7.

The observed flux densities in Figs. 1 and 2 were divided by  $(1+z)$  to normalize the values to a standard emitted bandwidth.

The points in Fig. 2 all fall on, or to the left of, a smooth envelope curve. Although the data may be incomplete for values of  $z$  approaching 2, it is thought to be substantially complete up to  $z = 1.5$ . At this value of  $z$ , an "envelope" source has a flux density of about five flux units at a frequency of 2,000 Mc/s. Consequently such a source even with a spectral index as low as 0.25 would be above the flux density limits of both the revised 3C catalogue and the Parkes surveys and so is likely to be included already. If this curve is really an envelope it indicates an upper limit to the intrinsic luminosity; the shape of the curve and the distribution of points along it would be related to the cosmological geometry and the evolutionary properties of the quasars.

The quasars lying on the envelope curve—their reference numbers are tabulated on the right hand side of Fig. 2—have similar characteristics. In general they have small angular size<sup>8</sup> and flat spectra; properties thought to be

Fig. 1. Bandwidth corrected flux densities versus red-shift for an emitted frequency of 500 Mc/s.

associated with young sources. This gives added weight to the existence of the envelope since such sources may well be in their most luminous phase.

It is interesting to note that the same relation does not appear so clearly at an emitted frequency of 500 Mc/s (Fig. 1). At lower frequencies, self-absorption will modify the luminosity and greater scatter can be expected. Presumably our relation demonstrates that the flux density at 5,000 Mc/s more accurately reflects the intrinsic properties of the emitter. A search for red-shifts greater than 2 might profitably be directed towards sources detected at frequencies above 1,000 Mc/s, the flux densities of which may be near the limit of sensitivity of the 4C catalogue at 178 Mc/s.

The shape of the envelope has been compared with the flux density variation, obtained from constant luminosity sources at different distances, in various cosmological models. With suitable choices of absolute luminosity, all models gave equally good fits to the data (see Fig. 3 for example). The absolute luminosities required, however, varied by up to a factor of 5. In all cases 3C 273B, which is beyond the scale of Figs. 2 and 3, lies to the left of the theoretical envelope.

We have examined the consequences of the model proposed by Longair<sup>9</sup> to fit the number counts at 178 Mc/s,

Fig. 2. Bandwidth corrected flux densities versus red-shift for an emitted frequency of 5,000 Mc/s.

Fig. 3. Comparison of the envelope data with luminosity variations in two cosmological models.

in which the mean intrinsic luminosity varies with epoch as  $P \propto t^{-2}$  in an Einstein-de Sitter universe. Fig. 3 shows the effect of including this variation in the flux density-distance variation, together with the "envelope" sources and the constant luminosity curve for an Einstein-de Sitter universe. We suggest that Longair's model is not applicable to our data, either because the upper limit to luminosity does not behave as the mean, or because the dependence on epoch is less at higher frequencies.

For an Einstein-de Sitter universe the upper limit to luminosity at an emitted frequency of 5,000 Mc/s appears to be about  $5 \times 10^{27} \text{ W c/s}^{-1}$ . This may be compared with the analysis by Ryle and Longair<sup>10</sup>, who suggest that quasars have a constant luminosity—at an emitted frequency of 1,407 Mc/s—for about  $10^5$  years and that there is only a small scatter in luminosity at this stage. The luminosity then declines rapidly. Our work confirms this, and shows that the scatter may be even less at high frequencies.

The data used for the "envelope" sources are given in Table 1.

Table 1. DATA FOR THE "ENVELOPE" QUASARS FREQUENCY OF EMISSION: 5,000 Mc/s

Source	$z$	Frequency of observation (Mc/s)	Flux density $10^{-28} \text{ W m}^{-2} \text{ c/s}^{-1}$
3C 9	2.012	1660	$1.7 \pm 0.2$
0056-17	2.125	1600	$1.4 \pm 0.2$
3C 147	0.545	3240	$11.0 \pm 0.7$
3C 196	0.872	2670	$7.5 \pm 0.5$
1116 + 12	2.118	1610	$2.0 \pm 0.25$
1127-14	1.187	2290	$6.5 \pm 0.6$
1148-00	1.982	1680	$2.8 \pm 0.3$
3C 273	0.158	4320	$34.0 \pm 1.9$
3C 279	0.536	3260	$11.9 \pm 0.75$

# Red-shift Magnitude Relation for Quasi-stellar Objects

by

M. S. LONGAIR  
P. A. G. SCHEUER

Cavendish Laboratory,  
Free School Lane,  
Cambridge

A red-shift magnitude correlation for quasi-stellar objects exists, but it does not imply a red-shift distance relation. If the red-shifts of quasi-stellar objects are cosmological their mean optical magnitude has changed with epoch.

THE apparent magnitudes of the brightest galaxies in clusters, or of radio galaxies, are extremely well correlated with their red-shifts. On the other hand, when the apparent magnitudes of quasi-stellar objects (QSOs) are plotted against their red-shifts, a broad scatter of points is found, and no correlation is obvious from inspection of the scatter diagram<sup>1</sup>. This lack of correlation has been variously interpreted as indicating that the red-shifts are not of cosmological origin, or merely that the QSOs have a wide dispersion in absolute magnitude. Red-shifts are now known for about 100 QSOs, and we thought it worth while applying some statistics to the problem. We found that, despite the large scatter, there is a highly significant correlation between apparent magnitude  $m_v$  and red-shift  $z$ .

There are three possible causes of a correlation between apparent magnitudes and red-shifts. (1) A red-shift (whatever its cause) changes the amount of radiation received from a source. (2) In the cosmological interpretation (and some of the local theories too) large red-shifts imply large distances, and therefore, through the inverse square law, large apparent magnitudes. (3) The luminosity of a source may be correlated with its red-shift. In the cosmological interpretation there could be a change in the mean luminosity of QSOs with epoch. In the various forms of local hypothesis there could be a physical connexion; for example, if the red-shifts are gravitational it might be that the sources with the deepest potential wells release the greatest energies.

After presenting the data we shall eliminate the first of these effects; then we shall investigate whether the data allow us to postulate the second without cancelling it out by the unknown effects of the third.

As the sample of quasi-stellar objects we have used all seventy-five objects in E. M. Burbidge's list<sup>2</sup> which lie north of declination  $-7^\circ$ . (There is now no good reason for the restriction  $\delta > -7^\circ$ , but as it excludes only nine of the eighty-four objects little harm has been done.) We are well aware that many selection effects occur in the processes of identifying QSOs and choosing those for which red-shift measurements are attempted—for example, bright QSOs, QSOs with strong radio emission, QSOs at high galactic latitudes and QSOs with strong emission lines are favoured. We have not, however, heard of or thought of any selection effect which would introduce a correlation between red-shift and apparent magnitude, without having any genuine astronomical significance.

Before proceeding to the correlations with red-shift, we note that there must be a wide dispersion in either the radio luminosities or in the optical luminosities of QSOs, for there is little correlation between their optical and radio magnitudes (Fig. 1). In fact there is probably a wide dispersion in both, for some individual objects vary by more than a magnitude at optical as well as at

Fig. 1. Optical and radio magnitudes of QSOs; this diagram shows only the 178 Mc/s radio flux densities. The two lines are the regression lines; the correlation coefficient is  $-0.149$ , and is not significant at the 5 per cent level.

high radio frequencies. Thus we should not expect a very obvious correlation between magnitudes and red-shifts, even if red-shifts are good distance indicators.

## Correlations between Red-shifts and Apparent Magnitudes

The red-shifts  $z$  of the QSOs in our sample are plotted against their apparent  $V$  magnitudes  $m_v$  in Fig. 2, their flux densities at 178 Mc/s,  $S_{178}$ , in Fig. 3, and their flux densities at 1,400 Mc/s,  $S_{1400}$ , in Fig. 4. The regression lines of  $\log z$  on  $m_v$  (or  $\log S$ ) and vice versa are also shown, and the correlation coefficients have been computed. A few objects of the sample are missing from Figs. 3 and 4, because some have been observed as radio sources at 1,400 Mc/s but not at 178 Mc/s, some at 178 Mc/s but not at 1,400 Mc/s, and a few ("radio-quiet") objects have not yet been observed at any radio frequency.

The correlation coefficient between  $\log z$  and  $m_v$  is  $+0.489$ , and the application of an  $F$  statistical test (see, for example, ref. 3) shows that the correlation is significant at the 0.1 per cent level. The correlation coefficients of  $\log z$  with  $\log S_{178}$  and  $\log S_{1400}$  are  $-0.198$  and  $-0.197$  respectively, and are not significant even at the 5 per cent level.

It has been reported that a correlation of radio magnitude with red-shift is found if one considers only sources with "flat" radio spectra<sup>4</sup> or only sources with small angular structure<sup>5</sup>. As there is a well known connexion between small source size and a deficiency in low-frequency radio emission (see, for example, ref. 6), we may consider these as one phenomenon, being in some sense a measure of the compactness of the radio source. We have tried re-plotting

Fig. 2. Red-shift versus  $m_v$ . The regression lines are shown; the correlation coefficient is +0.489, and is significant at the 0.1 per cent level. The values of  $m_v$  are taken from ref. 2.

Figs. 3 and 4 using different colours to represent sources with the ratio  $S_{178}/S_{1400}$  in various ranges, but without achieving any obvious departure from the appearance of chaos. We have also selected those sources for which observations with long baseline interferometers<sup>7</sup> or of interplanetary scintillation (L. T. Little, private communication) have shown that at least 50 per cent of the flux comes from a region much smaller than  $1 \times 1$  sec of arc; such sources do show correlation, the correlation coefficients in Figs. 3 and 4 being -0.611 and -0.815 respectively, both significant at the 1 per cent level.

### Eliminating the Effects of Time Dilation

The general formula for the flux density, at frequency  $\nu$ , of a source (or the apparent optical intensity observed through a given filter) in a homogeneous isotropic universe may be written<sup>8</sup>

$$S(\nu) = \frac{L(\nu)}{4\pi \left( \frac{\sin Ar}{A} \right)^2} \frac{L(\nu(1+z))/L(\nu)}{(1+z)} \quad (1)$$

Fig. 3. Red-shift versus  $S_{178}$ . The 178 Mc/s flux densities are taken, in order of preference, from refs. 15, 16 and 17. Full circles represent compact sources, in which more than 50 per cent of the flux comes from a region less than 1 sec of arc in diameter, as shown by interferometry or by interplanetary scintillation. Open circles represent other sources. The regression lines for all sources are shown as full lines; the regression lines for compact sources alone are shown dashed. Correlation coefficients: all sources -0.198 not significant at 5 per cent level. Compact sources -0.611 significant at 1 per cent level.

Fig. 4. Red-shift versus  $S_{1400}$ . The 1,400 Mc/s flux densities are taken, in order of preference, from refs. 18, 19 and 15. Symbols as for Fig. 3. Correlation coefficients: all sources -0.197 not significant at 5 per cent level. Compact sources -0.815 significant at 0.1 per cent level.

where  $L(\nu)$  is the power emitted per unit bandwidth, at frequency  $\nu$ ,  $r$  is the co-ordinate distance of the source and  $A$  is the curvature of the cosmological model. In this formula, the first factor represents the fact that the radiation is spread out over a spherical surface of area  $4\pi(\sin Ar/A)^2$ , and the second factor represents the change in the radiation due to the time dilation between source and observer. The latter factor includes: (a) the fact that radiation received at frequency  $\nu$  was emitted at frequency  $\nu(1+z)$  [ $L(\nu(1+z))/L(\nu)$ ]; (b) the diminished energy of each photon [ $(1+z)^{-1}$ ]; (c) the diminished rate of arrival of photons [ $(1+z)^{-1}$ ]; and (d) the contraction of the observed frequency band relative to the band in which the radiation was emitted [ $(1+z)^{-1}$ ]. What we now wish to emphasize is that the formula (1) is true whether the red-shift is cosmological or not; all the effects of time dilation remain the same, whether the red-shift is "cosmological", or an ordinary Doppler shift (as in Terrell's model<sup>9</sup>), or arises because the source is a puddle of hot gas at the bottom of a deep gravitational potential well (as in Hoyle and Fowler's model<sup>10</sup>), or a combination of these and other effects. The difference between the "cosmological" and other hypotheses appears only in the relation between  $r$  and  $z$  (see footnote). Each cosmological model predicts a definite relation between  $r$  and  $z$ ; if the red-shift is attributed to some other cause, there may be a different relation between  $r$  and  $z$ —for example, if QSOs were ejected from one local explosion and travel with constant velocity,

$$r = \text{constant} \times \frac{z(z+1)(z+2)}{(z+1)^2 + 1}$$

or no relation at all (for example, gravitational red-shifts).

Thus some correlation of  $\dot{S}$  with  $z$  must be expected, because of the second factor in (1), whether  $z$  is related to distance or not. The fact that there is a significant correlation between apparent magnitude and red-shift cannot be regarded as evidence in favour of the notion that  $z$  is a distance indicator. Fortunately the second factor in (1), which represents the effects of time dilation (or red-shift), involves only the observed red-shift and the observed spectrum of the source and can be computed without introducing any particular theory. It is therefore

In the "local hypothesis" the distances are so small that we can safely use the approximation  $(\sin Ar/A) = r$ . If the red-shifts are due to gravitation or to unknown causes, no ambiguity arises in the interpretation of  $r$ , but if the sources are moving and the Doppler effect makes a noticeable contribution to the red-shift, we must specify with great care the time at which the distance  $r$  is to be measured. If the source moves with constant velocity, the value of  $r$  which must be used in (1) is the distance from the source to the solar system, measured in the rest-frame of the source at the time when the radiation reaches us. If the source has a non-uniform velocity,  $r$  must be calculated as for a source which has moved since the radiation was emitted with the velocity which the real source had at that time. With this definition of  $r$ , the validity of (1) can be verified directly, but laboriously, by applying the rules of special relativity. It is obvious, however, that the value of  $r$  defined above is the radius of the sphere over which the radiation is spread, in the source's frame, when the radiation reaches us.

possible to investigate whether  $z$  is related to distance by plotting  $z$  (or  $\log z$ ) against

$$\begin{aligned} S'(v) &= S(v) \cdot (1+z) \cdot L(v)/L(v(1+z)) \\ &= S(v) \cdot (1+z) \cdot S\left(\frac{v}{1+z}\right)/S(v) \\ &= (1+z) S\left(\frac{v}{1+z}\right) \end{aligned} \quad (2)$$

or the corresponding average over the band covered by the  $V$  filter ( $m'_v$ ) in the optical case. (Note that the factor introduced in (2) is not the same as the "K correction".)

The radio spectra needed for computing  $S'(v)$  were provided by Dr P. J. S. Williams (private communication). For the optical spectra, the smoothed mean energy distribution derived by Sandage<sup>11</sup> from a study of the colours of forty-three QSOs has been used.

Figs. 5, 6 and 7 show  $m'_v$ ,  $\log S'_{178}$ , and  $S'_{1400}$  plotted against red-shift and the regression lines for these distributions of points. The most striking result is that the correlation between apparent magnitude and red-shift has disappeared completely, the regression lines being almost exactly perpendicular. The  $m'_v$ - $\log z$  correlation coefficient is +0.054, and is not significant even at the 5 per cent level.

Fig. 5. Red-shift versus  $m'_v$ . Correlation coefficient +0.054.

The radio data plotted in Figs. 6 and 7 show that high corrected flux densities ( $S'(v)$ ) are, if anything, correlated with large red-shifts. This result is not entirely unexpected; the source counts for QSOs indicate an excess of faint QSOs which, on the cosmological hypothesis, for example, must be explained as a cosmological evolutionary effect<sup>12</sup>.

The question which immediately arises is whether such apparently complete independence of  $m'_v$  and  $z$  is compatible at all with the idea that  $z$  is a distance indicator. We ask first of all whether the large dispersion in luminosities could obscure the distance dependence of  $m'_v$  sufficiently.

### The Effect of Luminosity Dispersion

The limit at about 19.5m imposed by observational selection, which is a vertical line in Fig. 2, is transformed by (2) into a curved line in Fig. 5 and can therefore affect the correlation in Fig. 5. In view of this complication, the simplest way to test the possible effects of a broad dispersion in luminosity on Fig. 5 is to compute analogous diagrams for model distributions of sources. Such calculations would be worthless, however, if we were to pick a

Fig. 6. Red-shift versus  $S'_{178}$ . Symbols as for Fig. 3. Correlation coefficients: all sources +0.295 significant at 5 per cent level. Compact sources -0.134. Not significant at 5 per cent level.

set of arbitrary models based on some tenuous theory, with numerous adjustable parameters. What we should like to do is to preserve the observed distribution of sources in  $z$ , and also to preserve the observed distribution in  $m'_v$ , and to introduce as an assumption only that  $m'_v$  and  $z$  are correlated through a relation between  $z$  and distance. This aim is achieved as follows. We assume that  $z$  is a good distance indicator, and that the form of the luminosity function (but not necessarily the density of sources) is independent of distance. We must also assume a particular relation between  $r$  and  $z$ , but the precise form of this relation is not critical. After all, we are hoping to discover whether or not  $r$  increases with  $z$  and we cannot expect finer details to have much effect on a diagram with a broad scatter of points. We have in fact used the relation

$$r = \text{constant} \times (1 - (1+z)^{-1}); A=0 \quad (3)$$

which is the correct relation if the red-shifts are cosmological and we live in an Einstein-de Sitter universe, but it would change the results little if we had simply used  $r=Cz$ . The remaining steps in the calculation are completely determined by the condition that we require (a) the same distribution in  $z$  as the observed distribution and (b) the same distribution in  $m'_v$  as the observed distribution.  $L(v)$  is computed for each observed source in Fig. 5, using equations (1) and (3), and a table of relative probabilities of  $L(v)$  is compiled by giving each source a weight  $W$  inversely proportional to the volume within which a source of its luminosity would have  $m'_v < 19.5$ . (This table does not show the true luminosity function for QSOs, for it is not derived from a complete sample. It does reflect the same selection effects as the sample in

Fig. 7. Red-shift versus  $S'_{1400}$ . Symbols as in Fig. 3. Correlation coefficients: all sources +0.282 significant at 5 per cent level. Compact sources -0.558 significant at 1 per cent level.

Fig. 5, and this is just what is required to satisfy condition (b).) To produce a diagram for comparison with Fig. 5, we take each of the seventy-five observed values of  $z$  in turn (ensuring (a)), and select a value of  $L(v)$  at random, a value of  $L(v)$  being selected with the appropriate probability  $W/\Sigma W$ . Then  $m_v$  is calculated; if  $L(v)$  leads, for the current value of  $z$ , to an apparent magnitude  $m_v > 19.5$ , we select another  $L(v)$ , and so on, until one  $L(v)$  is selected for which  $m_v < 19.5$ . Plotting the points ( $m'_v$ ,  $z$ ) found in this way, we obtain a diagram with identically the same distribution of red-shifts as the observed sample, and with the same mean distribution of  $m_v$ , but with the correlation between them implied by equation (3). The whole process was performed many times by computer and automatic curve plotter; the regression lines and correlation coefficients of the "model" diagrams were computed at the same time.

The procedure was tested by using a model diagram as if it were Fig. 5, to generate a luminosity function and a second generation of model diagrams; this was repeated for a number of first generation model diagrams and it was found that the distribution of correlation coefficients was the same in first and second generation model diagrams. The procedure was also tested by repeating it to higher and higher generations from the same initial diagram. If the procedure is sound, there should be no change in the statistical properties of the diagrams after the first generation, though first generation diagrams may differ from the observed diagram if (3) is not valid for real QSOs. In fact, some increase in correlation coefficient was noticeable after ten generations; this is readily explained, however, because if a particular luminosity class is missing from one diagram it never reappears in subsequent generations, so that the luminosity function gradually becomes narrower.

The remaining uncertainty in the procedure is that the luminosity function is computed from one sample of QSOs, so that there is an unknown uncertainty in the luminosity function. In particular, the correlations are fairly sensitive to the number of intrinsically faint QSOs.

Correlation coefficients were computed for many model diagrams (without physically plotting them), and Fig. 8 is a histogram showing their distribution. Correlation coefficients as low as that observed in Fig. 5 occur in only 17 out of 274 trials, and we conclude that the width of the luminosity distribution is unlikely to be a sufficient explanation for the lack of correlation between  $m'_v$  and  $z$ .

We have not attempted to compute model distributions for comparison with the correlations between red-shift and radio flux density for compact sources, shown in Figs. 6 and 7, because the numbers of sources are considerably smaller.

## Conclusions

There is a significant correlation between the apparent magnitudes of QSOs and their red-shifts. There is also a significant correlation between radio flux density and red-shift among QSOs which are very compact radio sources.

The correlations are largely accounted for by the effects of red-shift alone, without any dependence of distance on red-shift. The correlation with visual magnitude disappears entirely when  $\log z$  is plotted against  $m'_v$  instead of  $m_v$ . The correlations with  $\log S'$  incline to positive or negative values according to whether we take all QSOs or only the compact radio sources.

It is unlikely that the lack of correlation between the red-shifts and the apparent magnitudes  $m'_v$  corrected for the direct effects of red-shift can be explained by the luminosity dispersion alone.

There appear to be only two possible interpretations of these results. Either the distance is unrelated to the red-shift (at least the dependence is much weaker than the relation (3) over the range  $0.2 < z < 2.2$ ), or the luminosity increases systematically with red-shift so as to make

Fig. 8. Histogram of correlation coefficients computed, as described in the text, for models which have the observed distribution in  $m_v$ , and the observed distribution in  $z$ , but have the correlation between  $m_v$  and  $z$  required if  $z$  is a distance indicator, and the distribution of luminosities does not vary with epoch. The observed correlation coefficient is shown by a vertical dashed line.

$L(v)/(\sin Ar/A)^2$  roughly independent of  $z$ . In particular, if the cosmological interpretation of the red-shifts is correct, the optical luminosities must have been greater at earlier epochs; a similar evolution of radio luminosities has already been found necessary to account for the radio source counts<sup>12-14</sup>.

In principle it should be possible to test the dependence of  $r$  and  $z$  without the additional possibility of a dependence of  $L$  on  $z$ , by restricting the analysis to QSOs with small red-shifts. At present the number of QSOs with known red-shifts below, say, 0.3 is too small to make such a test significant.

We thank the director of the Mathematical Laboratory of the University of Cambridge, Professor M. V. Wilkes, for permission to use the TITAN computer, and Mr L. T. Little for communicating his observations of interplanetary scintillation in advance of publication. One of us (M. S. L.) is indebted to the Commissioners for the Exhibition of 1851 for the award of a research fellowship.

# Spawning of Haddock in Captivity

by  
A. D. HAWKINS  
K. J. CHAPMAN  
D. J. SYMONDS

Marine Laboratory,  
Department of Agriculture and Fisheries  
for Scotland,  
Torry,  
Aberdeen

The courtship behaviour and spawning habits of haddock have been observed for the first time. Whether the behaviour of haddock in the sea is the same remains to be determined.

KNOWLEDGE of the spawning behaviour of the haddock *Melanogrammus aeglefinus* is slight, despite its commercial importance. The time of spawning and the approximate areas in which it occurs are known from studies of the distribution and abundance of sexually mature fish and the planktonic eggs and larvae<sup>1-4</sup>. The conditions under which they spawn, however, usually at depths exceeding 100 metres, have so far prevented the direct observation of reproductive behaviour.

Recently, a small group of haddock kept in the aquarium of this laboratory have spawned and we are able to report on their behaviour. These fish, obtained by hand line fishing at Loch Ainort, Isle of Skye, in February 1967, were maintained in a 700 gallon glass-fronted aquarium tank supplied with recirculated seawater from a large reservoir. The temperature was maintained at 4–6° C until the end of March, when breakdown of the cooling unit resulted in a slow rise to 10–13° C. During April a single female fish paired with one of a group of three males and spawned repeatedly.

The behaviour within this group of fish immediately before spawning was striking, involving aggressive displays between male fish, and courtship displays between what appeared to be the dominant male and the single mature female. Throughout this preliminary behaviour all the male fish produced intense sound. We have previously reported on sound emission during aggressive encounters between haddock outside the breeding season, and have described the pulsed sounds produced in those circumstances<sup>5</sup>. Similar sounds were produced in this group of fish during frontal and lateral displays by males, and were accompanied by the extension of the vertical fins. The sounds and displays were made in response to the proximity of both male and female fish. The intense sound production throughout the spawning period correlates with the observation of Templeman and Hodder<sup>6</sup> that the sound producing muscles of this species are more highly developed in sexually mature fish, particularly in males.

The sounds produced during this study were recorded on magnetic tape, and oscillograms of these recordings are given in Fig. 1. We have previously remarked on the difficulty of avoiding acoustic distortion of low frequency sounds in enclosed bodies of water, and it should be noted that these oscillograms are affected by multiple reflexion of the sounds from the tank walls and water surface.

During aggressive behaviour the dominant male fish produced sounds for extended periods, moving about the floor of the tank with all fins extended. This appeared to initiate courtship by stimulating the female to approach. Although only one of the male fish courted and mated with the female, the other males present were sexually mature and showed signs of mating behaviour. With the female advancing on the dominant male, her vertical fins held against her body, there was an increase of the repetition frequency of the pulsed sounds produced by the male. As courtship proceeded, with the female following the dominant male about the tank, the repetition frequency

of the sounds increased further to give a humming sound. This leading behaviour by the male involved greatly exaggerated swimming movements and was accompanied by a marked change in pigmentation. Two accessory pigment spots developed along each flank behind the prominent 'thumbprint' characteristic of the species (Fig. 2).

Fig. 1. Oscillograms of recorded sounds produced by a male haddock during courtship. A. Sounds produced during solitary display by a male fish, heard as a fast knocking sound. B. Sounds produced by a male fish leading a female around the floor of the tank in a flaunting display, heard as a humming sound.

The flaunting display culminated in a sexual embrace. By a quick turning movement, the male came alongside the female and mounted her either dorsally or laterally. With both fish swimming rapidly around just off the bottom of the tank, the male then slid round the female to a ventral position (Fig. 3) and, in this attitude with the ventral surfaces of the two fish apparently held together by their swimming movements, they swam vertically upwards while releasing eggs and milt. The production of sound ceased during this embrace. After this brief spawning, the female fish retired to a secluded corner of the tank and the male returned to the floor, and started making a noise again.

The spawning act was repeated at nearly regular intervals, essentially in the same way, as summarized in Table 1. The interval between successive spawnings appeared to be determined by the female fish. Immedi-

Fig. 2. Flaunting display by a male haddock (in foreground) to a female, showing the development of accessory pigment spots on the flank of the male.

ately after eggs had been shed, all contact with male fish was avoided until the period immediately before the next spawning. By contrast, the dominant male fish showed no diminution of aggressive or courtship behaviour and on several occasions attempted to embrace the female within several minutes of spawning.

After each spawning, the pelagic eggs were collected from the tank using a fine mesh net. These eggs were retained for subsequent incubation but on five occasions their numbers were estimated. The estimates ranged between 7,500 and 16,500 eggs per spawning, with a mean of about 12,000, which gives an estimated total production of 168,000 eggs. This compares with a mean fecundity of 224,000 for a female of similar size and age, obtained by counting the number of developing ova in the ovaries<sup>2,7</sup>.

Estimates of the proportion of eggs fertilized were also

made by counting random samples taken from the tank immediately after spawning, and at intervals thereafter. The eggs were placed in a fine mesh bag and thoroughly washed with clean seawater to remove excess sperm, and then allowed to develop normally in fresh seawater up to the early stages of cleavage, when fertilized and unfertilized eggs could readily be distinguished.

A sample of eggs taken from the sixth spawning within 15 minutes of being shed showed that 93 per cent had been fertilized. A sample from the seventh spawning, however, taken within three minutes of being shed showed only 53 per cent fertilized. This increased to 83 per cent for eggs allowed to remain in the tank for 10 minutes, and 88 per cent for eggs left for 15 minutes. Samples taken from a later spawning (13th) showed in the first few minutes a reduced percentage of fertilized eggs (19 per cent after two minutes), though this increased later (59 per cent after 10 minutes, and 91 per cent after 13 minutes). Under the conditions in the tank, the immediate result of the spawning embrace is the fertilization of only a fraction of the eggs; many appear to be fertilized later by sperm in the water. It is possible, however, that our method of treatment of these eggs after liberation washed off sperm adhering to the outer membranes and thus reduced fertilization. The observation may not therefore provide a true indication of the efficiency of the spawning embrace in ensuring a high rate of fertilization.

The repetitive spawning we have observed for the female haddock is in accord with previous suggestions by several authors<sup>7,8</sup>, and similar repetitive spawning, though with longer intervals, has also been reported for the cod *Gadus morhua*<sup>9</sup>. Raitt has reported<sup>7</sup> the frequent presence in the lumen of ripe haddock ovaries of a number of large translucent ova (mean diameter 1.2 mm), while the ovary as a whole contained a larger number of smaller opaque ova (mean diameter 0.7 mm). He encountered very few ova of intermediate size and suggested that the larger ova were ripe and ready for shedding. The difference in volume between these ripe hyaline ova and the rest, together with the high fecundity of this species, suggests that only a limited number of ova can be allowed to ripen before shedding must occur. It is possible that the interval between successive sheddings is in part determined by the time of ripening of a number of the ova.

Table 1. SUMMARY OF SPAWNINGS BY CAPTIVE HADDOCK (*Melanogrammus aeglefinus*)

Date (April 1967)	Time (B.S.T.)	No.	Time since previous spawning	Estimated No. of eggs released	Remarks
9	—	1	—	—	Fertilized eggs collected from tank on 12/4 at 0900 h

Fig. 3. Embrace of a female haddock by a male (lower fish).

The spawning of these fish in captivity has been valuable in suggesting that the reproductive behaviour of haddock in the sea is complex, involving aggressive and courtship displays and culminating in a sexual embrace. The pigment change in male fish and the prominence played by sound production in courtship, together with the increased development of the sound producing apparatus in males during the breeding season, suggest that this preliminary behaviour plays an important part in reproduction. This could be verified by listening for these sounds in the sea on haddock spawning grounds. Our observations were necessarily limited by the small number of fish involved and the limited volume of water available, and it would be premature to suggest that courtship occurs just off the sea bottom. It is of interest, however, that Trout<sup>10</sup>, from the

evidence provided by trawl catches of this species, has suggested that spawning may be benthic or at least bathypelagic.

We are indebted to Mr R. Jones for providing us with the live fish used for these observations.

## Man, Vegetation and the Sediment Yields of Rivers

by

IAN DOUGLAS

Department of Geography,  
University of Hull

Is it possible to reconstruct erosion rates for past epochs when modern rates of erosion all reflect the hand of man to a greater or lesser extent?

MANY attempts have been made to estimate the rate at which the continents are worn away by measuring the sediment loads carried by rivers at the present time<sup>1,2</sup>. The validity of such attempts depends on the accuracy of the determination of modern erosion rates and on the extent to which modern conditions reflect those which

existed in the geological past. It is now realized that the annual sediment yield of any river can vary by as much as a factor of five from one year to the next<sup>3</sup> and that reliable estimates of erosion rates depend on long term records. Little account has been taken, however, of the impact of human beings on their environment and the

increases in sediment yield which are thereby produced. My reconnaissance studies of rates of erosion in a wide range of climatic conditions in eastern Australia suggest that present sediment yields of many rivers draining areas of long human settlement are far in excess of those which may have prevailed in the geological past.

I have estimated the rate of removal of suspended sediment by twenty-one streams in eastern Australia from observations of stream flow and suspended sediment load. These observations were made over a period of two years at infrequent intervals but over a wide range of hydrologic conditions. A relationship between discharge and sediment yield was established for each river and was used in conjunction with a flow duration curve based on data from a continuous water level recorder to estimate the annual suspended sediment yield. The annual suspended sediment yield of a river is expressed as the volume of sediment lost ( $\text{m}^3$ ) per unit area ( $\text{km}^2$ ) of the surface area draining to that river; this area is designated the catchment area. Similar calculations were made for another nine rivers in south-eastern Australia using long term records maintained by reservoir authorities. The general relationship between mean annual suspended sediment yields and mean annual run-off for these rivers is shown in Fig. 1.

Fig. 1. Relationship of suspended sediment load to run-off for the catchments studied in eastern Australia.  $\log_{10} Sy = 0.527 \log Qy + 0.0668$ .  $r = 0.499$  with 25 degrees of freedom and is significant at the 0.01 level.

The reliability of these estimates of sediment yields in Australia is confirmed by the earlier estimates of  $4.3 \text{ m}^3/\text{km}^2/\text{yr}$  as the rate of erosion of the area tributary to the Burrinjuck reservoir in New South Wales<sup>4</sup> and of  $11 \text{ m}^3/\text{km}^2/\text{yr}$  as the suspended sediment yield during flood periods from the Collie and Preston catchments in south-west Western Australia<sup>5</sup>. Both Fournier<sup>6</sup> and Strakhov<sup>7</sup> have produced maps showing rates of sediment loss from the land surface and Fournier indicates a rate of removal of suspended sediment from the north-east Queensland areas of  $750 \text{ m}^3/\text{km}^2/\text{yr}$  and for south-east New South Wales of about  $80 \text{ m}^3/\text{km}^2/\text{yr}$ , while Strakhov indicates rates of  $20\text{--}40 \text{ m}^3/\text{km}^2/\text{yr}$  for both districts. Although wide variations from these average rates would be expected, Fournier's values are a whole order of magnitude greater than those based on Australian data. Even bearing in mind the short period of investigation in Australia, it is unlikely that the values that I have obtained are erroneous to that extent.

The Australian rates compare with erosion rates from experimental plots under natural vegetation of  $1.0\text{--}$

$40.0 \text{ m}^3/\text{km}^2/\text{yr}$  quoted by Fournier and of  $10.5 \text{ m}^3/\text{km}^2/\text{yr}$ , measured on an experimental plot near Aix-en-Provence<sup>8</sup> and with rates of  $5.5\text{--}9.9 \text{ m}^3/\text{km}^2/\text{yr}$  from forested catchments in Oregon<sup>9</sup>. These results, together with an examination of the sources of Fournier's data, suggest that Fournier used streams draining areas much affected by changes in vegetation and soil stability induced by human activity and that the Australian observations provide closer estimates of natural erosion rates than do Fournier's world wide estimates. I therefore agree with Tricart<sup>10</sup> that Fournier's values are much too high for estimates of natural erosion and suggest that they represent accelerated erosion—the results of intense anthropic modification of the natural landscape. Because the Australian catchments were selected so as to avoid as much human disturbance as possible, the rates at which they are eroded are probably closer to the rate of natural erosion, even though some of them do contain areas modified by man. The effect of this modification can be seen in Fig. 1, where points 7, 11, 12 and 39 represent higher mean annual suspended sediment yields than those of other rivers with similar mean annual run-off. All these rivers have relatively large catchments in which the modification of vegetation and agricultural activity is greater than in the other catchments examined.

### Relief and Sediment Yield

Rates of erosion in mountainous areas are often greater than those in plains country. They may be as much as forty times greater in periglacial conditions<sup>11</sup>, where vegetation affords little protection to the soil, and up to fifty times greater in the mountains of Georgia (in the United States) than in the coastal plain<sup>12</sup>. Mal'tsev<sup>13</sup>, on the other hand, has found that the silt loads of Central Asian rivers increase downstream, and the volume of sediment removed per  $\text{km}^2$  diminishes with increasing altitude. Much the same happens in the Irrawaddy catchment<sup>14</sup>, where the silt load passing Mandalay is  $75.5 \text{ m}^3/\text{km}^2/\text{yr}$ , but below Mandalay  $347.0 \text{ m}^3/\text{km}^2/\text{yr}$  are derived from the Chindwin and a further  $507.0 \text{ m}^3/\text{km}^2/\text{yr}$  from the non-perennial streams of the dry zone, thus producing a total load at Prome of approximately  $310 \text{ m}^3/\text{km}^2/\text{yr}$  (ref. 15). On a much smaller scale in north-east Queensland, I have found that most of the load of Davies Creek was acquired after the creek had emerged from the steep upper catchment with its rain forests onto drier more sparsely vegetated plateau surfaces. In all these three examples, the streams are flowing from densely vegetated mountain areas into less densely vegetated, drier areas downstream and the effects of channel gradient and catchment slope on sediment yield are overshadowed by the difference in vegetation.

Thus although in some areas good correlations are found between the relief and maximum length of a catchment (expressed as a ratio of relief and length) and suspended sediment yield<sup>16</sup>, there is no generally applicable relationship of this kind. The factors which are significant in one area, or on one scale of investigation, may be of minor importance in another area or at a different scale. Relief factors are thus considered of little significance in the contrast between the sediment yields of the Australian catchments and those described by Fournier and others.

### Sediment Yields and Run-off

Comparisons of run-off and sediment yields show the combined effects of relief and vegetation. Although the correlation coefficient of  $0.499$  for the suspended sediment yield run-off relationship for the Australian data in Fig. 1 is significant at the  $0.01$  level and suggests that sediment yield increases with increasing run-off, data presented by Langbein and Schumm<sup>17</sup> suggest that sediment yield is a result of the influence of precipitation. Thus the yield of sediment increases with the amount of precipitation but this effect can be offset by the influence of vegetation, which increases in bulk with

effective annual precipitation. The data used to construct the upper curve in Fig. 2 lead to the approximate result

$$S = \frac{1.631 (0.03937P)^{2.3}}{1 + 0.0007 (0.03937P)^{3.3}}$$

where  $S$  is annual sediment load in  $\text{m}^3/\text{km}^2/\text{yr}$  and  $P$  is effective precipitation in mm defined as the amount of precipitation required to produce a known amount of run-off under specified temperature conditions. Following the same procedure as Langbein and Schumm, the lower curve in Fig. 2 has been calculated by the use of data from a wide range of published sources. Langbein and Schumm acknowledge that few of the rivers they have studied drain areas with their primeval environment and that most of the basins studied are in the centre of the United States—the very area in which Leopold<sup>18</sup> has reported that human activity has increased sediment yields by between two and fifty times. Langbein and Schumm's assertion that the shape, if not the quantities, of their curve may represent the natural balance between sediment yield and run-off may be questioned. The peak of the curve at a run-off of 30 mm may be exaggerated, for in these hydrological conditions the removal of vegetal cover permits great soil erosion by the few storms which produce significant run-off. This is described by Mundorff<sup>19</sup> in the Kiowa Creek Basin, Colorado, where mean annual run-off ranges from nothing to 15 mm and run-off and sediment yields from grassland soils are moderate to high and depend on the density of vegetal cover maintained during grazing or cultivation, whereas on forest soils the combination of surface litter, high infiltration rate and interception of the precipitation by the forest cover results in low run-off and sediment yield.

Fig. 2. General relationships between suspended sediment and run-off for streams studied by Langbein and Schumm and for a selection of rivers, including some major Asian rivers. ●, Catchments studied by Langbein and Schumm; +, catchments from other published data.

The shapes of the two curves in Fig. 2 may therefore reflect the "historical hangover" described by Chorley<sup>20</sup> and Anderson<sup>21</sup> in which the effects of changes in the equilibrium between climate, soils and vegetation, are delayed. For example, after forest clearance the roots hold the soil together until they rot some 5–10 yr later. In many of the semi-arid areas which now experience high sediment yields, the natural vegetation is a relict formation from wetter climates. Its failure to regenerate and the erosion of associated relict soils may be important causes of the high sediment yields. In more humid areas faster re-growth of vegetation and more regular precipitation make the effects of destruction of vegetation less drastic. The frequency of climatic oscillations in the recent past makes the present time an unsuitable period in which to make observations for extrapolation into longer periods of geological time.

#### Sediment Yield and Precipitation Distribution

Although the correlation coefficient of 0.499 for suspended sediment yield with run-off for the Australian catchments (Fig. 1) is significant at the 0.01 level, there

Fig. 3. Relationship of suspended sediment load to  $p^2/P$  for the catchments studied in eastern Australia.  $\log_{10} Sy = 0.737 \log p^2/P + 0.380$ ,  $r = 0.687$  with 25 degrees of freedom and is significant at the 0.001 level. ●, New South Wales catchments; x, Queensland catchments.

is a correlation coefficient of 0.687, significant at the 0.001 level, between these suspended sediment yields and the ratio of the square of the maximum mean monthly precipitation to the mean annual precipitation ( $p^2/P$ ) (Fig. 3). Fournier<sup>6</sup> has used world-wide data to demonstrate highly significant correlations between this measure of the amount of precipitation and the distribution and sediment yields of four classes of large catchment areas (Fig. 4). This measure of precipitation seasonality reflects not only the erosive impact of intense rainstorms

Fig. 4. Regressions of mean annual suspended sediment load against  $p^2/P$  ratio for catchments in eastern Australia and small catchments listed by Fournier, and Fournier's curves A, B, C and D, expressing general relationships between suspended sediment load and  $p^2/P$  ratios. Curve A applies to catchments of little relief when  $p^2/P$  is less than 20. Curve B applies to catchments of little relief when  $p^2/P$  is more than 20. Curve C applies to catchments of pronounced relief in all climates except semi-arid climates. Curve D applies to catchments of pronounced relief in semi-arid climates. The respective equations and correlation coefficients are: A,  $Sy = 6.14 - 49.78$ ,  $r = 0.800$ ; B,  $Sy = 27.12x - 475.4$ ,  $r = 0.960$ ; C,  $Sy = 52.49x - 513.21$ ,  $r = 0.950$ ; D,  $Sy = 91.78x - 737.62$ ,  $r = 0.980$ ; E,  $\log_{10} Sy = 1.356 \log x + 1.130$ ,  $r = 0.830$ ; F,  $\log_{10} Sy = 0.737 \log x + 0.380$ ,  $r = 0.687$ . All six correlation coefficients are significant at the 0.001 level.

such as that experienced during wet season storms in north-east Queensland, but also the nature of vegetation which becomes attenuated in areas of seasonal drought.

The contrast between the effects on sediment yields of evenly distributed precipitation of New South Wales and the highly seasonal rainfall of north-east Queensland is readily apparent from the distribution of points in Fig. 3. These Australian sediment yields are less than one-tenth of those in catchments with less than 2,000 km<sup>2</sup> in the USA, France and Syria examined by Fournier<sup>6</sup>, for which there is also a highly significant correlation with ( $p^2/P$ ) ( $r = 0.829$ , significant at the 0.001 level).

Vegetation growth and catchment erosions are both related to the magnitude and frequency of precipitation events. Irregularly distributed rainfall occurring in storms of high intensity and short duration fails to ensure sufficient water supply for the growth of dense vegetation and is also very effective in eroding the soil. The Fournier ratio ( $p^2/P$ ) expresses this variation well because the value of the ratio increases with both seasonality and total annual precipitation. High sediment yields are therefore to be expected in areas with marked wet and dry seasons, typical of the monsoon climates. Thus the observations from the Middle West of the United States and from Asia which have been used to construct Fig. 2 may be reconciled, both the relatively dry climates and the monsoon climates having higher ( $p^2/P$ ) ratios than temperate climates where the precipitation is more evenly distributed throughout the year. Thus the typical curve of the sediment yield run-off relationship is bimodal with a peak at 40–50 mm mean annual run-off and another at about 2,000 mm mean annual run-off (lower curve, Fig. 2).

These peaks become much more accentuated, however, when data from catchments with considerable human interference are used—the data from the USA, for example. Human interference also produces high sediment yields in the humid tropics, for example, 2,500 m<sup>3</sup>/km<sup>2</sup>/yr from the small Tjatjaban catchment in Java<sup>22</sup> which is greatly affected by cultivation of steep slopes. Although agriculturalists have long been aware of the effects of human interference in the humid tropics<sup>23</sup>, its implications for calculations of sedimentation during the geological past have been insufficiently examined. The assumptions made by Gilluly<sup>1</sup>, Judson and Ritter<sup>24</sup> and Mackenzie and Garrels<sup>25</sup> that the present sediment loads of rivers may be taken to represent those during periods of crustal evolution may be entirely unwarranted. The observation of present rates of erosion may provide us with no information directly relevant to the past, for human interference is so extensive and has spread so rapidly that we cannot be sure that observations relate to natural conditions. There is also the problem of the lag between weathering during cold periods in the Quaternary

and the removal of this material from slopes and valley floors. Recent investigations by Kirky in Scotland<sup>26</sup> and by myself in the Southern Tablelands of New South Wales have shown that much material now being removed from slopes and catchment areas is debris which accumulated during periods of Pleistocene periglacialation.

Without examining the complex physiographic, pedologic and hydrologic factors which affect erosion rates, there is sufficient evidence from the simple relationships between precipitation and sediment yield to demonstrate that the use of modern erosion rates for the reconstruction of past rates of sedimentation is full of difficulty. It is to be hoped that the present concern for nature reserves and the preservation of wild life will include sufficient areas of wilderness which can be used to measure geological processes and thus to enable the extent of man's role as a geological agent to be determined.

I thank the Australian National University for support and the Irrigation and Water Supply Commission, Queensland, the Water Conservation and Irrigation Commission, New South Wales, the Commonwealth Department of Works, Canberra, and the Snowy Mountains Hydroelectric Authority for hydrologic and sedimentation data.

## Single Stranded DNA in Lymphocyte Chromosomes

by  
LAWRENCE RAZAVI  
Harvard Medical School,  
Channing Laboratory  
Boston City Hospital,  
Boston

The distribution of single stranded DNA in lymphocytes has been examined by an immuno-fluorescence technique. Chromosomal genes seem to be active in these cells throughout the cell cycle.

In mammalian cells, single stranded DNA probably serves for replication<sup>1</sup>, as a primer for its own polymerase<sup>2</sup> and possibly as templates for the formation of RNA<sup>3-5</sup>. The location of such DNA in the nucleus, according to the

metabolism or life cycle of the cell, is therefore of interest because it may provide a structural foundation for some functions of chromatin. Conventional histochemical techniques, however, are not sufficiently specific<sup>6,7</sup> to

demonstrate those structures of chromatin which reveal its function. Antinucleotide antisera, on the other hand, are directed solely against short segments of single stranded DNA and, if labelled with fluorescein, provide alternative, stoichiometrically reliable, tracers of this substance in chromosomes.

Human peripheral blood lymphocytes<sup>9</sup> were grown in short term primary culture with phytohaemagglutinin. No antibiotics were used. Partial synchrony of initial mitoses<sup>10</sup> was improved by incubating cultures for 8 h at 37° C, keeping them at 20° C overnight and then re-incubating them. The first cell cycle reached mitosis after 48–50 h of incubation. Similar synchrony occurred in DNA synthesis, shown by the uptake of tritiated thymidine (Fig. 1).

Fig. 1. Rate of uptake of tritiated thymidine as a measure of synchronization in initial cell divisions of lymphocytes in primary culture. ●, Percentage of labelled mitoses; ○, mitotic index.

Isolated nuclei were prepared by hypotonic swelling at 100 mOsmoles for 20 min. They were fixed in Carnoy's fluid, preserving nucleic acids in a configuration vulnerable to attack by nucleases<sup>11,12</sup> and probably retaining antigenic sites similar to their natural form. They were air dried for 30 sec on a hot plate at 55° C. The slides were washed briefly in phosphate buffered saline (PBS, 0.14 molar sodium chloride; 0.0175 molar phosphate, pH 7.0) before subsequent treatment.

Rabbit antiserum against heat denatured DNA, electrostatically complexed with basic, methylated bovine serum albumin, was supplied by Drs Werner Braun and Otto Plescia of the Institute of Microbiology, Rutgers University.

The DNA contained mixed proportions of all bases, and the antiserum reacted in complement fixation systems as an antitetra-hexanucleotide<sup>8</sup>. Crystalline fluorescein isothiocyanate (Baltimore Biological Laboratories) was conjugated to the antiserum, using a fluor : protein ratio of 1 : 100. This ratio was critically necessary to avoid an alteration in the isoelectric point of rabbit globulin<sup>13,14</sup> sufficient to obscure results by non-specific electrostatic attraction between conjugate and chromatin. Labelled globulin was separated from other proteins and unbound dye by chromatography on 'DEAE-Sephadex', using PBS as eluate<sup>15</sup>.

Slides were stained in damp chambers for 1 h at 37° C, and washed in 500 ml. of PBS for 15 min with gentle magnetic stirring. Control slides were treated with DNase for 1 h at 37° C, in PBS containing 0.05 mg of magnesium chloride/ml. and 0.1 mg/ml. of enzyme. Control sera included antiserum absorbed with native or

denatured DNA together with standard immunofluorescence controls.

Specimens were illuminated by a Sylvania L 50 mercury vapour lamp through a dark field condenser. They were viewed through apochromatic objectives containing iris diaphragms and immersed directly in buffered glycerol, using a Zeiss UG2 (4 mm) exciter and No. 47 barrier filters, and were photographed through a UG2 exciter and No. 47 barrier filters on 'Agfachrome' film using 3 and 6 min exposures.

Interphase nuclei (Fig. 2) presented two patterns. Most frequently there was a collection of spots of various sizes throughout the nucleus on a very faint uneven background. This appeared in very few cells collected before 20 h, but the proportion increased thereafter and by 45 h most cells contained many spots. Their number increased with the age of the culture rather than with nuclear size. In early cultures the nucleolus was rarely stained (Fig. 2b), but older nuclei usually showed nucleolar fluorescence, occasionally multiple (Fig. 2c).

The second pattern occurred in small nuclei with a bright diffuse fluorescence often with a particularly bright zone at the nuclear membranes. Some cells were an irregular composite of both diffuse and spotted patterns, and this suggested that the diffuse reaction was an artefact. More intense heating of slides (such as 80° C for 1 min) promoted diffuse fluorescence and confirmed this suspicion.

Chromosomes in prophase fluoresced uniformly (Fig. 3a). There was some variability in intensity; certain chromosomes had brighter fluorescence at the periphery, and others contained intenser segments within the body of chromosomes (Fig. 3b). It was not possible, however, to distinguish given chromosomes from cell to cell by their reaction, though in each cell all chromosomes fluoresced to a greater or lesser degree.

In metaphase, there was bright fluorescence in discrete areas along the arms of chromatids with weak fluorescence between (Fig. 3c). In some spreads bright fluorescence appeared throughout all chromosomal material, but, as in interphase, heat promoted this diffuse reaction (Fig. 3e). Preparing slides without heating preserved the discrete reaction, but also gave poor separation of chromosomes.

The discrete fluorescent areas were irregularly shaped, some being small and circular, and others extending some way along the chromatid (Fig. 3d). Between one and five spots appeared in most chromosomes. In each nucleus most chromosomes reacted, but from cell to cell the distribution of reactions varied. Within a chromosome the spots were asymmetrically dispersed, and chromatids of a single chromosome (isologous) often reacted differently (Fig. 3d). The most frequent sites of attachment were telomeric or beside secondary constrictions. Centromeres were occasionally stained, but secondary constrictions and satellites were only reactive in strongly heated preparations (Fig. 3e).

There was no fluorescence if serum was absorbed with denatured DNA, but it occurred if native DNA was used. Nuclei treated with DNase no longer reacted (Fig. 3f). Methyl green (at pH 3.8) stained discrete areas densely in interphase nuclei, but not in chromosomes (Fig. 2d and e).

Ambivalence of such enzyme and histochemical controls has been encountered previously<sup>6,7,11,12</sup> and attributed to problems of their specificity and dependence on polymerization as well as chemical content of condensing chromosomes. If the strong attachment to localized spots is interpreted as specific reaction with areas rich in single stranded DNA, however, the distribution should agree with chromosome replication, and, possibly, template formation of RNA. Nucleolar fluorescence in young cells is consistent with template provision for active RNA synthesis found in phytohaemagglutinin cells during the *G*<sub>1</sub> period. Other nuclear and nucleolar reactions occurred as frequently as the uptake of labelled

Fig. 2. Distribution of fluorescein-labelled antinucleotide antiserum in interphase. (a) General view of spotted and diffuse patterns. Some cells are a composite of both patterns and the diffuse reaction is probably a heat artefact (see text). A metaphase complement is present at the top left. (b) Nuclei from a young (30 h) culture, one showing a spotted pattern with an unstained nucleolus, the other reacting diffusely. (c) Nucleus from a mature (48 h) culture with several large nucleolar-like areas showing fluorescence. (d) and (e) Methyl-green stains of similar nuclei with chromocentre-like areas staining densely.

Fig. 3. Distribution of fluorescein-labelled antinucleotide antiserum in mitosis. (a) Prophase chromosomes fluorescing throughout, with particular intensity at the periphery. (b) Prophase chromosomes showing general fluorescence but with some variation within their substance. (c) Metaphase chromosomes with discrete areas of fluorescence against a faint background. (d) Metaphase chromosomes at high magnification to show asymmetrical distribution of fluorescence. (The brighter material at lower right is cell debris fluorescing blue.) (e) Increased fluorescence in metaphase chromosomes which have been heated. (f) Decreased fluorescence in metaphase chromosomes which have been treated with DNase.

thymidine in the *S* period, and probably represent replication both among nucleolar organizers and other chromosomal segments. The faint background attachment is interpretable as a weak cross reaction between native DNA and antibody primarily directed against denatured DNA. The intensification of the background by heat, a phenomenon noted in other immunofluorescence work<sup>16</sup>, is probably, in this case, an artefact of heat denaturation.

These findings imply that the substrate is DNA in a template forming or replicating mode, during which short segments of the polymer reveal, *en passant*, successive antigenic sites. The presence of single stranded DNA in mitosis indicates a residuum or continuation of replication and template activity during condensation and segregation. The possibility of residual replication does not agree with autoradiographic evidence of incorporation of thymidine which ceases before the  $G_2$  period<sup>17</sup>. On the other hand, the possibility of continuing template formation concurs with the presence of uridine detected<sup>18,19</sup> in prophase and, possibly, metaphase; and would also be likely because of the genetic control of karyokinesis implied by non-disjunctional genes<sup>20</sup>. If chromosomal genetic activity continues during metaphase, furthermore, it seems reasonable that the active loci should occur telomerically or at heterochromatic junctions, because these parts of compact chromosomes may offer favourable sites for DNA to uncoil freely. Reactive sites vary between sister chromatids as well as between whole chromosomes or complements. This unbalanced content of single

stranded DNA must influence chromosomal dimensions and is reflected in certain asymmetrical characteristics of chromosomal behaviour, such as differential condensation rates within and between chromosomes<sup>21,22</sup>; unequal chromatids, such as seen in endoreduplication<sup>23</sup>, and dissimilar replication patterns in homologues<sup>17</sup>. Another consequence would be the statistical nature of homologue pairing by morphological<sup>24</sup> and autoradiographical appearances<sup>25</sup>.

These observations modify the proposition<sup>26</sup> that only a minor portion (about 20 per cent) of lymphocyte chromatin is active. In dividing cells, metabolic demands change through the cell cycle, and the active fraction may not always contain the same genes. Thus although there were complements in which all groups, including X chromosomes, fluoresced in both arms, this only reflects the replication implied by presence of RNA, detected before<sup>27</sup> throughout all chromosomes including both members of the X pair, and cannot be used to estimate the extent of inactivation implied by dosage compensation<sup>28</sup>. Fluorescence of interphase sex chromatin could not be distinguished, and activity in mitosis, where a minimum of gene control for self-condensation and spindle attachment may be required of each chromosome, need not imply activity during other periods of the cell cycle. Dosage compensation may represent an extension of the inactive phase in a cycle common to all chromosomes, but not necessarily maintained throughout mitosis. In much the same way, the needs of cell division in regenerating tissues<sup>29</sup> call into expression gene groups, detectable by

hybridization as single stranded segments of chromosomal DNA, which otherwise remain inactive.

In the circumstances of these experiments, it appears that in lymphocytes at least chromosomal gene activity is dynamically distributed in time and site. Its randomness suggests that there may be a more or less constant oscillation between repression and depression. Possibly dynamic genes are more easily modulated, and are more open to structural interchanges which occur somatically in normal<sup>30</sup> as well as aberrant cells. A structural basis for such behaviour is offered by the observation<sup>31</sup> that flexibility of hydrogen bonds within DNA allows thermodynamically feasible twists between open and coiled states. In the uncoiled state, phosphate repulsion between strands would serve to separate many fluctuating single stranded segments as they surface, without disturbance of the overall structure. Such a system would reveal, transiently, the short segments of single stranded DNA seen in the experiments represented here.

Continual gene availability is a pre-requisite of genetic systems in which control and structural elements are separated<sup>32</sup> and in which epigenetic control over differentiation<sup>33</sup> or phenotypic expression in heterokaryons<sup>34</sup> is mediated through extra-chromosomal factors, possibly similar to ribosomal regulators of bacterial RNA and protein synthesis<sup>35,36</sup>. Similarly, the observations reported here provide a possible basis for systems in which the DNA molecule acts as a coding device only, while mutation resides in euchromatin-heterochromatin transitions<sup>37,38</sup>, and gene expression is under the permissive control of a cytoplasm in contact with the demands of the environment<sup>39-42</sup>.

Finally, these antisera offer resolution and specificity not available with natural antinuclear sera from autoimmune disease. The valuable work of previous workers<sup>16,43,44</sup> showed that the use of natural antisera in cytological analysis was only limited because they contain unknown mixtures of antibodies. Artificially specified antisera may prove of greater interest in tracing chromosomal constituents and their relation to chromosomal aberration<sup>45,46</sup>.

## A Limiting Microfibril Model for the Three-dimensional Arrangement within Collagen Fibres

by  
ARTHUR VEIS  
JOAN ANESEY  
SHIRLEY MUSSELL

Northwestern University,  
Medical School,  
Chicago

Consideration of evidence of the mode of polymerization of collagen monomers provides a more detailed picture of the three-dimensional organization of the fibrils in a collagen fibre.

In his classic review Bear<sup>1</sup> described the hierarchies of structural order within a macroscopic collagen fibre in terms of aggregates of fibrillar units of increasing size. Several investigators have tried to give a more detailed

picture of the three-dimensional organization of the fibrils in terms of the packing of the fundamental macromolecular units, the collagen monomers. These attempts, based primarily on X-ray diffraction and electron microscope

Fig. 1. The quarter-stagger, end-overlap arrangement of collagen monomer units according to the proposal of Petruska and Hodge<sup>10</sup>.

observations, have been very fruitful, but have not been entirely successful. Further consideration of evidence on the mode of intermolecular polymerization of collagen can provide still further insight into this problem.

Although the point has been questioned recently<sup>2</sup> we begin with the assumption that the collagen monomer unit has the same rod-like form in the native fibril that it has in solution<sup>3-5</sup>. The rods, approximately 3000 Å long and 15 Å across, are asymmetric or polarized in the sense that the regions containing polar and apolar side chains are not distributed uniformly along the length of each rod. This is shown quite clearly in electron micrographs<sup>6-8</sup> of positively stained segment long spacing precipitates. Hodge and Schmitt<sup>9</sup> demonstrated that the native fibre was composed of monomer units oriented so that all monomers had the same polarity but with each monomer displaced by one-quarter of its length from its nearest neighbours. More recently, Petruska and Hodge<sup>10</sup> showed that each molecule is 4.4 times the length of the fundamental native repeat of 695 Å and modified the "quarter-stagger" arrangement with the suggestion that there was no head-to-tail association of chains in a continuous array. There was, rather, a "hole region", 0.6 times the length of the basic repeat distance ( $D$ ), between monomers in the same axial disposition. It was proposed that an end-region overlap, 0.4  $D$  plausibly, as illustrated in Fig. 1, stabilized the fibre assembly, in agreement with the observations of Olsen<sup>11</sup>. This arrangement very plausibly explains the cross-striation pattern seen in electron micrographs of native collagen fibres in a two-dimensional representation. As Smith<sup>12</sup> and others<sup>13,14</sup> have shown, however, one cannot make a three-dimensional arrangement which maintains a quarter-stagger relationship between every nearest neighbour monomer unit. Smith<sup>12</sup> deduced that only about 67 per cent of monomer contacts in the native structure could be in quarter-stagger agreement. Grant *et al.*<sup>15</sup> arrived at the similar conclusion that parallel monomer units could not have quarter-stagger arrangements throughout a fibril. On the other hand, the appearance of a systematic set of holes within a collagen fibril seems well established<sup>10</sup>.

These representations treat the collagen monomer as if it were a rigid rod which has a radial symmetry of its properties at any particular point along the rod, that is, in directions perpendicular to the rod axis. This is obviously not the case. Each monomer unit is composed of three peptide chains, two of which (designated  $\alpha 1$ ) are essentially identical while the third peptide strand,  $\alpha 2$ , has a different composition. Each chain is wound as a left-handed helix,

but the three helices are wound into a compound right-handed helix which makes a complete turn every 90 Å. At any particular level along a rod, the chains may be disposed as indicated in Fig. 2a or 2b.

As the individual strands wind up the compound helix, the positions of the chains shift with respect to the external co-ordinates of the monomer rod, so that, as shown in Fig. 2c, the side chain dispositions also vary. The monomer rod can be thought of, in essence, as a helically striped pole in which one band (the two  $\alpha 1$  chains) is twice as wide as the other (the  $\alpha 2$  external projection). Positive staining with cationic and anionic electron dense stains shows that both positive and negative side chain functional groups appear in the same regions in native fibrils. Hence, to assure fibril stability, the packing of the monomer rods must be such that attractive electrostatic interactions between rods are maximized. To achieve this, the side chains of the adjacent molecules must be suitably disposed and this implies that a rotational phasing perpendicular to the monomer unit long axis must exist in addition to the axial quarter-stagger.

Insight into the nature of the rotational phasing comes from studies of the intermolecular polymers found in native collagen fibres and on the distributions of molecular species. The presence of intermolecular cross-linkages in mature collagen has been amply demonstrated<sup>16,17</sup>. Two features are particularly important for the present discussion. First, the intermolecular polymers fall into distinct weight classes:  $2 \times 10^5$  ( $\beta_{22}$ )<sup>16</sup>  $3 \times 10^5$  ( $\gamma$  components)<sup>16,18,19</sup>, and  $1.2 \times 10^6$  ( $\delta$  components). Veis *et al.*<sup>18</sup> pointed out the fact that polymers with molecular weights intermediate between  $\gamma$  and  $\delta$  were not detected and suggested that there was some natural unit, corresponding to a tetramer of collagen monomers, which was highly internally cross-linked and hence particularly stable. Subsequent work<sup>19</sup> using high resolution disc electrophoresis, ultracentrifugation and carboxymethyl cellulose chromatography confirmed the absence of intermediate size polymer species.

The second point concerns the nature of the  $\gamma$  components. Veis and Anesey<sup>19</sup> showed that all four possible  $\gamma$  components were present in extracts of mature collagen:  $\gamma_{111}$ ,  $\gamma_{112}$ ,  $\gamma_{122}$ , and  $\gamma_{222}$ . Of these, the intermolecular species  $\gamma_{111}$  and  $\gamma_{222}$  were quantitatively the principal components, and they appear to be polymerized in distinctly different ways. Chromatography of gelatines rich in these components have been carried out on carboxymethyl cellulose according to the technique of Veis and Anesey<sup>19</sup> and the appropriate fractions taken. After desalting, the  $\gamma_{111}$  and  $\gamma_{222}$  fractions were dissolved in dilute, salt free 0.1 molar acetic acid and renatured by cooling solutions to 4°C. Addition of salt free ATP to the  $\gamma_{111}$  solutions resulted in precipitation of copious amounts of segment long spacing collagen, Fig. 3, which in both positive and negative staining shows the presence of spools of monomer length,  $\sim 3000$  Å. In sharp contrast to these results, the identical renaturation and precipitation procedures did not lead to SLS collagen when applied to  $\gamma_{222}$  gelatin. Fibrous

Fig. 2. Cross-section representations of a collagen monomer. a, The conventional representation at a particular level, showing the two  $\alpha 1$  chains and the  $\alpha 2$  chain; b, a triangular representation of the triad cross-section. The corners are marked with chain type designations. The lines emanating from the corners indicate the positions of the side chains; c, three successive residue levels in the compound helix, showing how the relative chain and hence side chain orientation vary with respect to a fixed frame of reference as one progresses up the compound helix.

precipitates were obtained in this case which gave the native type of periodicity, Fig. 4.

One conclusion drawn from this set of observations is that  $\alpha 1$  chains can be aligned and intermolecularly cross-linked with their lengths in register. On the other hand, the  $\alpha 2$  chains must be aligned and intermolecularly cross-linked in the quarter-stagger array. In aligning helices of the same pitch, it can readily be seen that if there is some regular periodic variation in property at any particular helix position in each helix, then alignment of the two helices to bring these sites together at some common point will also align all other equivalent sites. To abut common sites, however, one helix must be rotated about its long axis. These considerations indicate that if a particular pair of  $\alpha 2$  chains on adjacent molecules are properly disposed for cross-link formation, then  $\alpha 2$  chain sites must come together periodically at other places in equally suitable juxtaposition. There are therefore no problems in constructing intermolecular polymers of  $\gamma_{222}$  type in a quarter-stagger structure.

The appearance of  $\delta$ -component polymers with no species intervening between it and the  $\gamma$ -type polymers, as pointed out earlier, suggested that a tetramer of monomer rods represented a fundamental packing unit within a fibril. Olsen<sup>20</sup> noted that native fibrils in negative stain electron micrographs appeared to be composed of sub-filaments with diameters representing one to four monomer molecules. A suitable structure, preserving the quarter-stagger-overlap ordering, is a right-handed helical arrangement of four monomer units displaced successively from the origin by 0, 1, 2 and 3 fundamental repeat distances,  $D$ , along the axis and  $90^\circ$  about the axis. A second  $\delta$ -unit

Fig. 3. Segment long spacing collagen prepared from  $\gamma_{111}$  gelatine isolated by carboxymethyl cellulose chromatography. Stained with phosphotungstic acid, pH 2.0, and saturated uranyl acetate. ( $\times 45,000$ .)

Fig. 4. Native type fibres produced from a  $\gamma_{222}$  rich gelatine fraction isolated by carboxymethyl cellulose chromatography. Stained with phosphotungstic acid, pH 2.0, saturated uranyl acetate. ( $\times 45,000$ .)

Fig. 5. Models of the limiting microfibril. *a*, The fundamental tetrad of collagen monomer units. The  $\alpha 2$  chains have been blackened. Each monomer is displaced by  $1D$  from the  $A$  end of the adjacent monomer unit; *b*, two tetrads packed together into a continuous filament showing the positions of the  $0.6D$  holes or spaces and the overlap between tetrads.

tetramer then fits directly into the first tetramer, leaving a  $0.6D$  unit hole and a  $0.4D$  overlap, and this process may continue to make microfibrils of indefinite length in which each monomer is in the quarter-stagger with respect to its neighbours. The objections of Smith<sup>12</sup> and Grant *et al.*<sup>15</sup> to the overall quarter-stagger structure can be accounted for by the side by side packing of the limiting fibrils. The in-register packing of fibrils has the advantage that in its interfibril cross-linkages can lead to the  $\gamma_{111}$  type of side by side polymer. The model is illustrated in Fig. 5.

This model appears to be in accord with the behaviour of collagen fibres. In contrast to the sheet-like strictly quarter-stagger arrays, it provides for the filament character of the collagen fibril. When fibrils are swollen in acid one sees at the swollen fraying ends readily separable small discrete fibrils. There is also the proper variation in fibril density as the system of holes pervades even the smallest unit so that the density differences described by Grant *et al.*<sup>15</sup> are present at all structure levels. Acid-swelling of the collagen can be assumed to occur by solvent imbibition and separations of the limiting microfibrils without disruption of the basic spacings. Burge *et al.*<sup>21</sup> showed that in spite of 400 per cent increases in width and 100 per cent increase in volume of the fibres the first order X-ray diffraction equatorial spacing perpendicular to the fibre axis increased from only 13 to 15 Å in the pH range 2–12. The constraints preventing unlimited swelling and dissolution of the fibrils would be the interfibril bonds. In one of the earliest studies of the depolymerization of insoluble collagen, Veis and Cohen<sup>22</sup> suggested that there had to be at least two independent systems of transverse

intermolecular cross-linkages in mature insoluble collagen. The present model represents these two modes of polymerization, one set (the  $\alpha$  2-system) joining the tetramers into the limiting microfibrils and the other set (the  $\alpha$  1-system) joining the fibrils into the infinite insoluble network characteristic of insoluble collagen. Finally, while fibrils reprecipitated from salt or acid solutions of the soluble collagens may well appear to have aggregated in an essentially random fashion as suggested by Grant *et al.*<sup>15</sup>, it seems unlikely that the *in vivo* aggregation of collagen could be random as well. Tissue specific fibril packing, degree of polymerization and modes of cross-linking all appear to be too well controlled to have resulted from an initial random monomer axial alignment.

## A Membrane Effect of Basic Polymers dependent on Molecular Size

by  
HUGUES J.-P. RYSER

Department of Pharmacology,  
Harvard Medical School,  
Boston, Massachusetts

Albumin penetration into animal cells is stimulated by basic polyamino acids and DEAE-dextran, and increases with the size of the polymers. This dependence on size suggests that multiple attachment of a macromolecule to the membrane is necessary for biological function.

TUMOUR cells in culture will take up protein molecules such as albumin and ferritin<sup>1-4</sup>, and this transport can be enhanced by the presence of protamine, histones and basic polyamino-acids in small concentrations<sup>5</sup>. Studies of the uptake of albumin by cells of sarcoma S-180 suggest that polymers of L-ornithine, L-arginine, L-histidine and D-lysine of high molecular weight can act in amounts of 0.01  $\mu\text{g}/\text{ml}$ . and can produce a ten- to thirty-fold increase in the uptake of albumin in concentrations of 3  $\mu\text{g}/\text{ml}$ ., but in the same conditions free amino-acids and diamines such as spermine and spermidine with a small molecular weight have no effect on albumin uptake<sup>5</sup>. The question therefore arises as to whether a minimum molecular size is necessary to cause stimulation. We have set out to examine the supposed relationship between biological activity and molecular size, and have also examined the possibility that basic macromolecules which are not peptides—DEAE-dextran, for example—may possess a similar ability to stimulate albumin uptake. (DEAE-dextran (diethylaminoethyl-dextran) was tested in the sizes of molecular weight 2,000,000 (commercial preparation) and molecular weight 80,000. The latter was a gift from the Research Division of Pharmacia, Upsala. The ratios of glucose:DEAE of these two preparations were 2:1 and 2:7 respectively.)

We used the technique developed in this laboratory<sup>1,5</sup> to follow the uptake of labelled albumin into tumour cells. Sarcoma S-180 cells were grown in monolayer cultures rinsed with serum-free Eagle's medium and incubated for 60 min at 37° C in 1 per cent horse serum in the presence of albumin labelled with iodine-131 and basic polymers. (The activity of the incubation mediums varied between  $2.5 \times 10^5$  and  $5.2 \times 10^5$  C.P.M./ml.; the specific activity in 1 per cent horse serum was of the order of 5–10  $\mu\text{C}/\text{mg}$ .) They were then rinsed once with Earle's saline, detached by trypsinization and the cell suspension was washed

twice in saline and treated with 5 per cent trichloroacetic acid. The acid insoluble fraction was washed, counted on 'Millipore' filters, and its specific radioactivity was determined<sup>1</sup>.

The effect on albumin uptake of poly-L-ornithine and poly-L-lysine with different molecular weights in concentrations of 3  $\mu\text{g}/\text{ml}$ . is shown in Table 1, column A. (This is ten times less than the concentration which, in the same conditions, produces the first signs of abnormal cell

Table 1. CORRELATION BETWEEN SIMULATION OF ALBUMIN UPTAKE AND MOLECULAR WEIGHT OF POLYMERS BELONGING TO FOUR HOMOLOGOUS SERIES

Homologous series	Molecular weights ( $\times 10^{-3}$ )	No. of experiments	Effect in % increase above control uptake	
			A (3 $\mu\text{g}/\text{ml}$ .)	B ( $1.5 \times 10^{-6}$ molar)
Poly-L-ornithine	200	(9)	2,680	2,680
	130	(4)	2,200	1,430
	90	(3)	1,718	774
	45	(5)	976	220
	4*	(7)	509	10
Poly-L-lysine	225	(5)	872	960
	125	(4)	796	496
	50	(2)	417	104
	20	(5)	600	60
	6-7	(2)	528	17-7
Poly-D-lysine	3-1	(2)	597	8-2
	113	(9)	1,912	1,078
	65	(9)	1,211	360
DEAE-dextran	19	(9)	590	58-3
	2,000	(3)		890
Spermine ‡	80†	(3)	33-7	13-5
	0-20	(14)	4	0

The effect is expressed as per cent increase above the uptake of control cells. Column A gives the stimulations caused by 3  $\mu\text{g}/\text{ml}$ . of each compound. Column B gives the effect of a  $1.5 \times 10^{-6}$  molar solution of each compound.

\* Poly-D-L-ornithine.

† Because of its slightly lower degree of DEAE substitution and its greater ash content, this dextran was used in the corrected concentration of 3-78 instead of 3-0  $\mu\text{g}/\text{ml}$ . The dextran MW  $2 \times 10^6$  was tested directly at the concentration of  $1.5 \times 10^{-6}$  molar.

‡ Includes data obtained with 10, 30 and 100  $\mu\text{g}/\text{ml}$ .

reaction, that is, a beginning detachment from the glass. Unless otherwise mentioned, all concentrations of basic polymers were  $3 \mu\text{g/ml.}$  On a weight basis ( $3 \mu\text{g/ml.}$ ) the effects of the different poly-L-lysines are rather similar, but those of poly-L-ornithine decrease sharply at a molecular weight of less than 90,000. It had already been observed<sup>5</sup> that identical amounts of poly-L-lysine varying in molecular weight between 15,000 and 70,000 do not have markedly different effects. When, however, the effects of the L-lysine and L-ornithine polymers are expressed on a molar basis (column B), they decrease sharply with decreasing molecular weight and spread over a range of more than  $10^3$ . Column B is derived from column A by correcting for the differences in molarity. (This conversion is justified by the finding that the dose-effect curves of homopolymers of different sizes converge towards the same threshold and that in all cases  $1.5 \times 10^{-8}$  molar lies well above threshold. Furthermore, an identical relation between effect and size was observed when poly-L-ornithines of different sizes were used in the same experiment in concentrations of 0.3 and  $30.0 \mu\text{g/ml.}$ ) When plotted on a double log scale against the molecular weight, the figures in column B fall on two straight lines (Figs. 1 and 2, solid lines). Several molecular sizes of poly-D-lysine were available for testing. Their effect is also shown in Figs. 1 and 2 (closed circles). It is evident that they fit the curve for poly-L-lysine better than the curve for poly-L-lysine. This confirms the earlier observation that poly-D-lysine is a more powerful stimulant of albumin uptake than poly-L-lysine, and is comparable in effect to poly-L-ornithine<sup>5</sup>.

The intersection of the solid lines of Figs. 1 and 2 with the abscissa indicates that the minimum molecular weights required to elicit the membrane effect are approximately 500 and 900 for  $1.5 \times 10^{-8}$  molar solutions of the poly-amino-acids; they correspond to tetra- and octa-peptides. They are greater than the molecular weight of the polyamines spermine (203) and spermidine (146), which may explain why those amines are inactive in the stimulation of albumin uptake<sup>5</sup>.

In spite of the totally different nature of its repeating unit, DEAE-dextran is able to mimic the effect of basic polyamino-acids. Table 1 gives some results obtained with DEAE-dextran of two different molecular sizes. Both on a weight and molar basis, the substituted dextrans are less active than the polyamino-acids, but as with the polyamino-acids, the DEAE polymer of smaller size has a smaller effect. The relation between action and size of the two dextrans is represented graphically in Fig. 1 (interrupted line to the right). Obviously the same general

Fig. 1. Correlation between activity and molecular weight of polymers in homologous series of poly-L-ornithine (open circles), poly-D-lysine (closed circles) and DEAE-dextran (squares). Ordinate: stimulation of albumin uptake expressed in per cent increases above control uptake. The lines of best fit intersect with the abscissa at MW of 900 (DP, 8 ornithine) and 11,000 (DP, 52 glucose).

Fig. 2. Same correlation as in Fig. 1 for a homologous series of poly-L-lysine (open circles). The poly-D-lysine values of Fig. 1 are redrawn for comparison (closed circles). Intersection at molecular weight 500. Tested in amounts of  $3 \mu\text{g/ml.}$  or more, spermine (SP) and spermidine (SPD) had no significant effect.

correlation exists for both classes of compounds, although they differ markedly in the molecular size required for comparable effects. Thus the smallest effective molecular weight of DEAE-dextran is of the order of 11,000, corresponding to fifty-two glucose units, compared with 500 to 900 for the polyamino-acids.

These observations represent an interesting example, possibly the first, of a biological effect on the cell membrane which is clearly related to the molecular size of the agent responsible. It is reminiscent of the data of Kat-chalsky *et al.*<sup>6</sup> concerning the concentrations of polylysine required to agglutinate red blood cells; five times as much polylysine was required when the degree of polymerization of homopolymers was decreased from 200 to 16. The simplest way to account for the relation between the size and activity of polymers in a homologous series is to assume that stimulation of albumin uptake requires the attachment of the polymer molecule by more than one basic group and that the effect increases with the number of bonds between the polymer and the cell membrane. In the conditions of our experiments, the polyamino-acids are in the form of flexible random coils<sup>7,8</sup>, so that the number of basic groups likely simultaneously to reach the plane of the cell surface can be expected to increase with molecular size.

If the notion of multiple attachment is correct, the activity of a polymer should decrease when the spacing between amino groups is increased in the primary structure and when the molecule as a whole becomes more rigid because of its tertiary structure, and this expectation appears to be borne out by the data on DEAE-dextran. The dextrans used in this study have a glucose to DEAE ratio of 2:1 and 2:7, which fixes the distance between basic groups at approximately twice that in the amino-acid polymers. This doubling of the interval, together with the rigidity caused by the intramolecular cross-linking characteristic of dextrans, may explain why a larger molecular size is necessary for action.

The same structural factors may also explain why histones are considerably less active than homopolymers of most basic amino-acids<sup>5</sup>. Because only between a quarter and a third of the amino-acids in histone molecules are basic, the average distance between  $\text{NH}_3^+$ -groups will be correspondingly longer than in homopolymers of basic amino-acids. Furthermore, parts of the histone molecules are considered to be in the  $\alpha$ -helical form<sup>9</sup>, which, with the appreciable content of hydrophobic amino-acids, confers a degree of rigidity on the histone structure that is lacking in basic homopolymers. The ineffectiveness of a strongly charged diamine such as spermine suggests that a three-point attachment to the membrane may be

necessary to elicit a response. This requirement could be met by a tetrapeptide.

The nature of the interaction between basic polymers and cell surfaces is not known, but recent physico-chemical studies on isolated tumour cell membrane<sup>10,11</sup> are relevant. Thus part of the membrane protein is in the  $\alpha$ -helix form, and it has been suggested that some helical segments of the molecule have orientation normal to the plane of the membrane and reach into the lipid layers, whereas other segments reside in the surface layer. A polybasic compound attached to the cell membrane may be able to influence the conformation of membrane proteins by changing the charge distribution on segments of peptide chains. Multiple attachment to neighbouring points of the membrane could strain the membrane structure, and one basic macromolecule could be expected to interact in this way with several structural proteins and to have a profound effect on membrane structure and function. Although new data on protein orientation and conformation in the cell membrane<sup>10,11</sup> offer an improved basis for understanding the effect of basic polymers on cell membranes, there is also evidence of small amounts of RNA in the plasma membrane of tumour cells<sup>10,12</sup>. Because of the physiological association of basic proteins and nucleic acids in the nuclei, it is worth suggesting that a comparable interaction may occur between polyamines and membrane-RNA.

The relation between activity and molecular size described previously also throws new light on the mechanisms underlying pinocytosis. Previous electron microscope studies have shown that cells of Ehrlich ascites carcinoma and sarcoma S-180 take up large proteins

such as ferritin by pinocytosis, and there is evidence that in other tissues labelled albumin is taken up by the same mechanism. Electron microscopic studies in progress have shown that poly-L-ornithine in the condition of these experiments increases the uptake of ferritin and labelled albumin in pinocytotic vesicles (unpublished results of Revel and Ryser). It is suggested that the multiple attachment of a large basic polymer to membrane constituents and the conformational changes resulting from this interaction constitute a stimulus sufficient to induce pinocytosis.

## Tolerated Infection with the Sub-bacterial Phase of *Listeria*

by  
PHYLLIS E. PEASE

Department of Bacteriology,  
University of Birmingham

Auto-immune and malignant disease in man may be the result when tolerance to the mycoplasma phase of *Listeria* is disturbed.

DESCRIPTIONS of micro-organisms associated with the lesions of auto-immune and malignant diseases of man have been, and still are, so frequently made that only a small selection of the published literature can be included in the references of this paper. Claims that these may represent the causative agents of the diseases have been treated with great reserve. In similar diseases of animals, however, where experimental studies can more readily be made, there is much evidence for the role of infective agents.

There are several reasons for this sceptical attitude, but an important one has been the lack of an acceptable hypothesis to replace the classical theories of microbial or virus infection in these diseases. Such a hypothesis must account for the apparent anomalies, and especially for the failure to identify a distinctive pathogen, regularly associated with each condition; for the frequent absence of a demonstrable immune response; and for the obvious roles of carcinogens, hormones, shock effects and similar non-infective agents. Suspicion has been fostered by evidence both of contamination of tumours *in vivo* and of cultures *in vitro*, especially, in the latter case, with micro-organisms such as mycoplasmas and diphtheroid bacteria that are commonly presented as potential pathogens. These are found in eggs, animal sera and tissue cultures, all of which have been extensively, but not exclusively, employed in the studies in question.

I believe that these difficulties and apparent anomalies can be explained. Comparison of published evidence with the results of investigations in this laboratory provides evidence to support the hypothesis that some—possibly but not necessarily all—forms of auto-immune and neoplastic disease in man can be mediated by disturbance of immune tolerance between the host and a widely distributed micro-parasite.

Such a hypothesis need not depend on or require the association of a specific pathogen with each pathological condition. The requirements for an infective agent in the role of mediator of auto-immune or neoplastic disease are: (a) that the infection be either congenital or acquired in early infancy, so that immune tolerance is achieved; and (b) that the base sequences of host and parasite nucleic acids be similar, so that episome units may be transferable. In effect, among the micro-organisms that might play this part, the sub-bacterial phase of *Listeria* (*Listerella*) seems best qualified to fulfil the requirements, and it is apparent that many of the best-attested descriptions of suspected infective agents in these diseases refer to phases of *Listeria*, the widespread occurrence and potential importance of which have only recently begun to be understood<sup>1-3</sup>, and are still far from fully recognized.

There is already a theoretical background for this argument. I have reasoned<sup>4</sup> that auto-immune disturbance can result from upset of tolerance, caused by sub-

cellular elements of bacteria, acting as episomes in body cells and Hotchin<sup>6</sup> suggested that "docile human agents" could cause chronic disease in late life, as the lymphocytic choriomeningitis virus does in mice. These refer to auto-immune disease, but suggestions that infective agents in neoplastic disease may act in a similar manner have also been made. There is evidence that defective rather than complete viruses are associated with malignancy<sup>6</sup>, that is, they act as episomes; they have appropriate base sequences<sup>7</sup>, and most, if not all, of them are either congenital or chiefly affect very young animals<sup>8,9</sup>.

*Listeria* can be found in the blood and tissues of a very high proportion of humans (as well as other animals) in a form very difficult to detect and recognize; it seems often to be congenitally acquired and is thus tolerated immunologically. The base ratios of its DNA are similar to those of its human host, in the region of 40 per cent<sup>10-12</sup>. In addition to the results of investigations made in this laboratory, and of other surveys of *Listeria* as such<sup>1,2,13</sup>, it is apparent from the descriptions of latent blood infections with micro-organisms, unidentified but exactly corresponding to *Listeria*, that it occurs in a large proportion of even apparently healthy persons<sup>14,16</sup>.

Murray<sup>2,13</sup>, a discoverer of *Listeria*, gives as general characters of this inadequately studied micro-organism that it is widely distributed among the individuals of at least twenty-seven species of animal; that it is liable to be confused with other bacteria or completely overlooked; and that it exhibits certain very unusual, puzzling and obscure appearances in its host-parasite relationship. These include a tendency to cryptic persistence of infection and to immune tolerance by the host. The classic sign of *Listeria* infection is monocytosis, but this is recognizable only in a minority of cases. Infective mononucleosis in man is believed by some authorities to be caused by a combined infection of bacillary *Listeria* with a virus<sup>17</sup>, which may well be the bacterial and the mycoplasma-like phases of the same organism. The term mycoplasma may be regarded, in this context, as synonymous with the *L*-form, because the sub-bacterial phase of *Listeria* possesses the characters of a mycoplasma, in its ability to form filaments of typical size and appearance, in its tendency to parasitism, and in its antigenic constitution, which is discussed later in this article.

The occurrence of what I now believe to be *Listeria* has been very widely reported from cases of rheumatic and neoplastic disease but its identity has not been established, and because of the very diverse identifications that have been made, the significance of these findings has not been recognized by bacteriologists and pathologists in general. Bacteria, especially cocci, diphtheroids and mycoplasma, have been isolated from arthritis and other auto-immune diseases<sup>14,15,18-23</sup>. Acid-fast bacilli, actinomyces, spirochaetes, even fungi and sporozoa, as well as viruses and, once more, mycoplasmas, have been reported in, and sometimes isolated from, neoplastic disease including leukaemia<sup>14,21,24-33</sup>. Most if not all the morphological appearances described, including the viruses (Fig. 1), are within the range of variation of *Listeria*, and in some cases these investigators have given recognizable descriptions of its morphological cycle<sup>14,16</sup>.

Comparison of strains of *Listeria* from eight cases of infectious mononucleosis, and two of *L. monocytogenes* from the National Collection of Type Cultures, with the illustrations and descriptions of previous workers, made it apparent that the appearances previously recorded are characteristic of newly isolated *Listeria*. The same organism was isolated from all the ninety-five human subjects examined, but there was much variation in the ease with which this could be done, depending on the apparent degree of infection. Isolations from serum or serous fluid could most easily be made by adding 1-5 ml. of the inoculum to 10 ml. of a simple fluid medium (for example, Brewer's medium) so that the inoculum itself provided the necessary enrichment; but it must be emphas-

ized that the early stages of culture would not be recognized as bacterial growth by anybody unfamiliar with the practical problem.

From the lesions of twenty-one cases of rheumatoid arthritis and eight of mitral stenosis, and from the blood of nine cases of malignant tumours and six of leukaemia and Hodgkin's disease, it was relatively easy to isolate *Listeria*, frequently in the bacterial phase (that is, "diphtheroids"). These figures are small, but are presented for the purpose of confirming the identity of the micro-organisms that have been described from similar sources in the past. From the blood of forty-nine healthy subjects it was isolated almost invariably in the mycoplasma phase, and the apparent degree of infection was less consistent, being so slight as to be detected only with difficulty in at least two-thirds of these. The remainder were moderate, except for three, not clinically ill, who were heavily infected and from whom the bacterial phase could be isolated. All specimens of the serum of the horse, ox and calf, and of the eggs of the domestic fowl, were infected in some degree, but these were chiefly pooled samples, and so the true incidence is not known. It is thus presumably congenital in the fowl, and may be so in man, because it is a common cause of abortion<sup>1</sup>, and was isolated, during this investigation, from the organs of four out of four miscarried infants.

It must be emphasized that this high degree of infection in healthy subjects is in accordance with current theories of infectious mediation of auto-immune disease<sup>4,5</sup>, and some oncogenic viruses have also been shown to be comparably widely distributed in healthy members of the affected species, and to cause tumours only exceptionally<sup>8,9,34</sup>. The healthy subjects should not be regarded as controls, as in classical infective theory.

The mycoplasma phase was isolated, either alone or with the bacterial phase, sometimes (as in healthy subjects) in very small quantities, as cysts, about 4  $\mu$  in diameter, staining poorly with basic dyes, but showing weakly Gram-positive granules in a pale, Gram-negative matrix. These are readily mistaken for dried debris and thus overlooked, especially if scanty, but in the electron microscope they can clearly be recognized as aggregates of very tiny spheres (Fig. 1). In culture, growth sometimes proceeds rapidly, so that in the course of about 48 h typical mycoplasma filaments develop from the cysts, or this process may be delayed for several weeks. Cultures that are both initially scanty and then slow to grow are liable to be discarded as negative. There is little doubt that this has happened many times in the past. Transformation into the bacterial phase sometimes occurs in a few days, or may do so only on prolonged culture. About 20 per cent of the isolates made on this occasion eventually reverted to typical *Listeria* morphology.

This transformation has been figured by other workers, notably Villequez<sup>16</sup> and Alexander-Jackson<sup>14</sup>, who did not, however, identify *Listeria* but regarded their isolates as new species associated principally with cancer, although they both also recognized a possible link with arthritis. The clearest and most complete illustration is that given by Turner<sup>35</sup> in his description of the life cycle of the organism of bovine pleuropneumonia; the chief difference being that the bacterial phase, whereby *Listeria* is usually recognizable, is more completely suppressed in the pleuropneumonia organism.

The inclusion of egg or serum to culture media is desirable for the isolation of this organism, but this presents a serious problem, because all such material is liable to be contaminated, and may show visible cysts even if these have been killed by inspissation, thus confusing the reading of early or slow growing cultures. Tissue cultures or other media containing native serum, even if filtered, are quite unsuitable for either isolation or growth purposes, because the chance of their containing living, filter-passing elements of this or similar mycoplasmas is very high. To achieve

Fig. 1. Two phases of *Listeria monocytogenes*. Partially disrupted cyst, composed of tiny granules, resembling oncogenic viruses in size and form, and bacterial form. Electron micrograph, gold-palladium shadowed. ( $\times 12,500$ .)

satisfactory control, the only serum that can be used is that under examination on each occasion.

### Causation Hypothesis

Infection by *Listeria* seems to be universal, at least in certain communities, and because the diseases concerned are chronic and affect human beings, the suspected pathogen cannot be related to the pathological conditions by classical infective theory, nor can Koch's postulates be satisfied. In fact, a hypothesis for infective mediation of auto-immune and neoplastic disease does not require that they should be. Any infective agent that fulfils the requirements could, in theory, play the role equally well. *Listeria* is a clear candidate, because, in addition to being tolerated immunologically, and showing evidence of nucleic acid similarities with man, it is so notably widespread; and because the appearance of its smaller elements (Fig. 1) is very similar to that of the tumour viruses illustrated by Gross<sup>8,9</sup> and others. This should be considered in the light of Alexander-Jackson's suggestion<sup>10</sup> that the Rous sarcoma virus is the mycoplasma phase of a bacterium.

Thus using *Listeria* as an illustration, and the tumour viruses<sup>8,9,34</sup> and LCM virus<sup>5</sup> as models, the hypothesis may be stated in the following terms.

The mycoplasma phase of *Listeria*, lacking the strong antigens of the cell wall, and probably congenital in the host, is tolerated; it is widespread in the body, so that any tissue can be affected when tolerance is disturbed. Loss of tolerance could cause auto-immune disease, by the mechanism suggested by me previously<sup>4</sup>, taking the form of rheumatic disease if the invading episome produced streptococcal antigens, which do occur in *Listeria*<sup>1</sup>. In contrast neoplastic disease could involve too complete a tolerance, with the episome acting the part of the defective viruses or mycoplasmas that are believed to be associated with malignancy<sup>6</sup>.

Evidence of a connexion between *Listeria* and neoplastic disease is afforded by its possession of I blood antigens<sup>35</sup>. Disturbance of the normal balance between adult I and foetal i antigens has been observed in these conditions<sup>37</sup>. It is apparent that an excess of the semi-tolerated I could result in such disturbance of balance, resulting in a tendency towards suppression of I and selection of the foetal i. Thus an embryonic type, especially of blood cell, may be permitted to develop in the immunologically mature person. Increased tolerance could also result in the removal of suppression of the bacterial phase, so that recognizable bacteria appear in the lesions of neoplastic disease, as other people<sup>14,25,26</sup> have noted.

It has been reported that stimulation of the immune response by transduction can produce a regression of tumours in experimental animals<sup>38</sup>.

As I have already pointed out, the hypothesis does not demand that a specific pathogen should be associated with each disease. The possibility that *Listeria* may be the infective agent mediating these types of pathological condition has been fully examined in this paper, but, in fact, the common human mycoplasmas (whether or not these are actually related to *Listeria* phylogenetically<sup>39</sup>) are well adapted to play the same part. They also possess streptococcal antigens<sup>39</sup>, and their infections are marked by the occurrence of I:i antigen disturbance<sup>37</sup>.

The role of carcinogens in this hypothesis is extended rather than reduced, as might at first be imagined. Carcinogens are believed to act on the nucleic acids of the host<sup>40</sup>. If so, they must be equally capable of affecting those of the parasite, and producing a defective, potentially malignant episome. Carcinogens and hormones are known to induce malignancy in previously benign infections with oncogenic viruses<sup>8,9</sup>. It must be accepted that environmental and heritable factors are important principal or concomitant causes of auto-immune and neoplastic disease, but the evidence suggesting that an essential infective element exists in some such conditions is now very considerable. This can be correlated with the other known facts by a hypothesis such as is now proposed.

I thank the Arthritis and Rheumatism Council for assistance.

Quinoid secretions are found to have an unexpectedly wide distribution in tenebrionid insects which live on stored food. The seventeen species involved include the common grain, flour and fungus beetles.

A VARIETY of insect secretions which comprise toxic chemicals have received attention in recent years<sup>1,2</sup>. Our interest is specifically directed to those of common stored-food pests. We report on the occurrence of quinones in grain, flour and fungus beetles of the family Tenebrionidae: *Alphitobius diaperinus* (Panz.) and *laevigatus* (F.); *Alphitophagus bifasciatus* (Say); *Gnathocerus cornutus* (F.) and *maxillosus* (F.); *Latheticus oryzae* Waterh.; *Palorus ratzeburgi* (Wissm.) and *subdepressus* (Woll.); *Tenebrio molitor* L. and *obscurus* F.; *Tribolium anaphe* Hint., *brevicornis* (Lec.); *destructor* Uyttenb.; *castaneum* (Herbst); *confusum* Duv.; *confusum* mutant *msg*; and *madens* (Charp.). These species are the principal surface feeding insect pests of cereal staples and related food products. We have developed a polarographic technique which has enabled us to detect quinoid toxin in all these beetles and to define the secretions electrochemically. The method, which permits the quantitative determination of as little as  $10^{-7}$  g of quinone, will be described elsewhere.

Insects were made available from stocks at various laboratories in Canada, Great Britain, and the United States. They were maintained on a mixture of wheat flour and wheat germ until used.

Fig. 1 shows polarographic curves obtained from insects *Tribolium madens* and *brevicornis* (upper waves). The half-wave potentials of  $-12$  mV and  $-14.5$  mV versus saturated calomel electrode agree with that for tetratoxin from *Tribolium confusum* and *castaneum* and *Latheticus oryzae* (Table 1), as well as for synthetic ethylparabenzoquinone<sup>3</sup>. *T. madens* and *brevicornis* are found in mills and warehouses, infesting wheat, barley, oats, chicken feed and honeycomb, among other foods. They are similar in appearance, size and habits to *T. confusum* and *castaneum*, which belong to the same genus. They have, however, a surprisingly high quinone content, amounting to as much as  $384$   $\mu\text{g}/\text{beetle}$  (Fig. 1, Table 1). The chemical constitutes as much as 5 per cent of their body weight. Catalytic reduction performed in the polarographic sample compartment with  $\text{Pd-H}_2$  proceeded with ease, was complete and produced a clear pattern of reversibility of the electrode process (lower waves in Fig. 1). Log plots of  $i/(i_d - i)$  versus mV (not shown in Fig. 1) were straight and revealed a two electron transfer. The reciprocals of the slopes were 0.031 and 0.030, respectively.

Polarograms for two species of pests, *Gnathocerus cornutus* and *Latheticus oryzae*, belonging to other genera, are pictured in Fig. 2. These beetles, slightly less than an eighth of an inch long, are widespread throughout the world, infesting rice and flour mills, also milo, beans, sorghum, raisins mixed feeds, and other ordinary foods.

Table 1. QUINONES IN STORED FOOD INSECTS

	$E_1$ , mV versus saturated calomel electrode	$\mu\text{g}/\text{insect}$						$\mu\text{g}$ of $Q + HQ$ , average/ insect
<i>Tribolium madens</i>	$-14.5 \pm 1.5$	Q: 197	146	216	123			
		HQ: 6	9	8	5			179
<i>Tribolium brevicornis</i>	$-12 \pm 2$	Q: 384	309	262	254	318	295	
		HQ: 10	11	8	10	14	12	329
<i>Tribolium castaneum</i>	$-13 \pm 1$	Q: 71	43	52				
		HQ: 5	7	9				62
<i>Tribolium confusum</i> (wild type)	$-13 \pm 1$	Q: 57.9	69.0	53.1	36.6	62.1		
		HQ: 1.2	2.4	1.5	2.4	3.0		57.8
<i>T. confusum</i> (mutant <i>msg</i> )	$-13 \pm 1$	Q: 0.0	1.1	0.0	2.2	0.3		
		HQ: 1.1	1.9	1.8	2.3	1.4		2.4
<i>Gnathocerus cornutus</i>	+58	Q: 0						
		HQ: 6						6
<i>Latheticus oryzae</i>	$-12 \pm 1.5$	Q: 3	1					
		HQ: 8	2					7

Figures were computed from polarographic data (consult text). Q, quinoid; HQ, hydroquinoid. Reciprocal slopes,  $\log i/(i_d - i)$ , in all cases  $0.031 \pm 0.002$ .

The straight line log plots, both with reciprocal slopes of 0.030, again evidence reversibility of the electrode process, with a two electron transfer. For these beetles, however, the waves are partly or entirely anodic (hydroquinone) and the diffusion currents are less than  $1.5$   $\mu\text{amp}$ . The

Fig. 1. Polarograms of quinone in insects *Tribolium madens* and *Tribolium brevicornis*. Upper waves, original secretions. Lower waves, samples reduced with  $\text{Pd-H}_2$  (consult text).

Fig. 2. Polarograms of quinoid secretions in insects *Gnathocerus cornutus* and *Latheticus oryzae*. Log plots  $i/(i_d - i)$  versus potential show reversibility and two electron transfer of the electrode process (consult text).

half-wave potential found for *Gnathocerus cornutus* is +58 mV versus S.C.E., that is, close to that of benzoquinone, the standard oxidation-reduction potential of which is more positive by 0.06 V than that of simple alkyl-parabenzoquinones<sup>4</sup>.

Previous investigations of the chemical composition of quinoid insect secretion, which were based on the isolation of volatile substances from insects by atmospheric pressure or vacuum sublimation, have in no instance produced evidence of the existence of hydroquinone in the glands of these beetles<sup>5-7</sup>. The present method, in contrast, facilitates the detection of hydroquinone, as is shown by the anodic portions of the waves in Fig. 2. This finding is interesting because of the discovery of the melanotic stink gland (*msg*) mutant of *Tribolium confusum*<sup>8</sup>. We have studied the mutant (Table 1), and the data of Engelhardt *et al.*<sup>9</sup> concerning the low quinone content were confirmed, while hydroquinone, reportedly absent, was discovered in some of the beetles as the sole quinoid component of the secretion.

The uniformity of the half-wave potentials of the various insect secretions suggests that most of them are simple alkyl-parabenzoquinones comparable with, or identical with, those previously established in *T. castaneum*<sup>6</sup>. Attention is directed towards large quantitative differences among species, and to the quantitative variability in individuals of any one species. The latter is attributed to the different ages of the specimens, which were taken from random age populations<sup>10</sup>.

Additional species listed in the introductory statement were screened with the method and quinones were found in all of them. The identity of the polarographically detected quinones was in each case further substantiated by a potassium iodide starch test, consisting of crushing a beetle on KI-starch paper that had been moistened with dilute sulphuric acid. Blue spots developed on the paper where it had absorbed the insect secretion, with the intensities of the coloration closely corresponding to the heights of the diffusion currents for any one species of insects.

The results show that quinones, and hydroquinones, are ubiquitous in tenebrionid stored food insects. While

the quantities of these chemicals total only a few  $\mu\text{g}$  to about 0.5 mg/insect, the number of infestants thriving on human food is enormous<sup>7</sup>. A report has appeared in Yugoslavia<sup>11</sup> on infestation of sunflower seeds, which are a principal source of edible oil in eastern countries. The survey of 95,390 tons of stored seeds provides the information that forty thousand million insects contaminated this commodity, eighteen thousand million of which were *Tribolium castaneum*. Computing the amount of quinone on the basis of the supply of 55  $\mu\text{g}$  in this beetle (average of three *Q* values in Table 1), 2,200 lb. of the toxicant were in contact with the food. In addition, 290 lb. of hydroquinone (Table 1) were present.

It has long been known that *Tribolium* infesting wheat flour leave the latter contaminated with coloured toxin-protein conjugates<sup>12,13</sup>. The quinone is taken up avidly. Flour merely exposed to the vapours of the toxin binds 350 p.p.m. of it within 60 min<sup>10</sup>. In the reaction, quinoid protein conjugates plus hydroquinone are formed according to the mechanism first described by Fischer and Schrader<sup>14</sup>. Ladisch has recently published a detailed experimental study on the interaction of the naturally derived toxin with various amino-acids and peptides<sup>15</sup>.

Alkyl-parabenzoquinones are recognized wide-spectrum toxicants<sup>16</sup>. Hydroquinone, likewise considered harmful and deleterious, has not been approved as a food additive. Ladisch<sup>17</sup> and Hueper<sup>18</sup> have enumerated a variety of carcinogenic and potentially carcinogenic quinones, among which are the quinones secreted by common flour beetles. Several more specific reports concerning acutely toxic, allergenic, teratogenic, carcinogenic and anti-fungal activities of these insect secretions have also been published<sup>3,7,17,19-21</sup>. The present results, reflecting the unexpected wide distribution of quinones in food pests, clearly establish the need for further research into the problem.

## LETTERS TO THE EDITOR

## ASTRONOMY

## Radio Source W49 and Anomalous OH Emission

THE radio source W49 has become of increasing interest recently because of its association with regions of strong anomalous OH emission at radio wavelengths<sup>1-6</sup>. The source is situated in the galactic plane in a direction of high optical obscuration so that information has to be obtained entirely at radio wavelengths. Observations on the continuum have shown the source to be an HII region and in addition spectral line observations at 21 cm wavelength<sup>7</sup> and at the 109 $\mu$  hydrogen recombination line at 6 cm (ref. 8) have indicated that the distance is about 14 kiloparsec. A measure of the electron temperature and of the velocity distribution of the ionized gas has also been obtained from the recombination line observations. This communication presents some new high resolution observations obtained with the recently completed 150 ft radio telescope of the Algonquin Radio Observatory at a wavelength of 2.85 cm, supplemented by observations at 9.45 cm. These results when considered in conjunction with laboratory measurements suggest that the anomalous OH emission observed from the source might be explained as the result of the formation of OH in an electronically excited state by a two-body process.

Fig. 1 shows the results of the observations, presented as a contour diagram for the wavelength of 2.85 cm, and was produced from scans taken across the region, after corrections had been made for atmospheric refraction, for pointing accuracy of the telescope as determined from observations on the source 3C84, and for the change from the epoch of 1966.8 to the standard epoch, 1950.0. The source designated B is the non-thermal source, and the source designated A is the thermal source W49, according to the classification of Mezger and Henderson<sup>9</sup>, whose observations at a wavelength of 6 cm had previously resolved the region into two principal components. With the higher resolution obtainable with the 150 ft. telescope, it is

Fig. 1. Contour diagram for the region surrounding source W49. Contour units are antenna temperature. The crosses represent the positions of the individual sources and the black rectangles are the positions of enhanced OH emission. The velocities are those of the chief features of the enhanced line emission. The weak areas of emission to the north of source A are due to a coma lobe of the telescope.

Fig. 2. The full line represents the mean of scans in both directions across the peak A1, at declination  $9^{\circ}01'1$  taken on October 22, 1966. The broken line shows the resolution of the source A into two components, A1 and A2.

obvious that A is complex and can be seen to consist of a main peak with some degree of elongation in the direction of increasing right ascension. The two low level peaks to the north of the main peak result chiefly from a coma lobe of the telescope, but the other additional low level areas of emission are believed to be real. Declination scans across the main peak, at the wavelength of 2.85 cm where the beamwidth is 2.8 min of arc and at 9.45 cm where the beamwidth is 9.2 min of arc, show that the broadening of the half-power beamwidth in each case amounts to 0.5 min of arc. Right ascension scans through the main peak at the wavelength of 2.85 cm show an asymmetry such that, for increasing right ascension, the intensity rises to a peak but then tails off more slowly, as shown in Fig. 2 which is a scan in right ascension at declination  $9^{\circ}01'1$ . If symmetrical curves are fitted to the drift scans at various right ascensions and declinations it is possible to show that the apparent elongation of the chief source is consistent with the presence of the two sources, A1 and A2, in the positions shown in Fig. 1. The sources are separated in angle by 2.8 min of arc—in other words by the half-power beamwidth—in a direction approximately at right angles to the galactic equator. It is obvious that this is not necessarily a unique solution, and the chief source could consist of a ridge of emission, or an elongation, along the direction joining the assumed sources A1 and A2. On the other hand, the fact that the source A1 has small dimension in declination suggests that it might have a similar dimension in right ascension.

Accordingly, a model for this principal feature of the region would consist of two sources each with a minimum dimension of 0.5 min of arc, with corresponding linear dimensions of about 2 pc. Within the limits of experimental error, the continuum spectrum appears to be flat, and this, in conjunction with the presence of hydrogen recombination lines, would indicate that the emission is thermal. The assumption that the optical depth over the whole region is less than unity leads to values for the mean electron densities of less than  $1,230 \text{ cm}^{-3}$  and  $560 \text{ cm}^{-3}$  for A1 and A2 respectively. On the other hand, it is difficult to relate such a simple model to the apparent broadening of the beamwidth at the two wavelengths. The increases in beamwidth by a constant amount indicate an increase of diameter at the longer wavelength. This in turn suggests that if the source is purely

thermal, then it must be optically thick in places, at least for the wavelength of 9.45 cm and possibly also for the wavelength of 2.85 cm. Such considerations lead to electron densities in some areas which must be at least as high as  $10^4 \text{ cm}^{-3}$ . Because  $\text{H II}$  regions will in general be expanding, the density of the neutral gas outside the region will be similar in magnitude to that of the ionized region, and the two sources would then consist of fairly dense  $\text{H II}$  regions, produced by the associated young hot stars, embedded in a larger diameter  $\text{H I}$  region. Evidence for the latter is indicated by the surrounding diffuse area, which would be the weakly ionized gas.

Of added interest is the position of the areas of greatly enhanced OH emission relative to the two principal regions. The more intense components of the 1.665 Mc/s line as determined by Rogers *et al.*<sup>10</sup> are also plotted in Fig. 1, and it is clear that the 21 km/s feature is closely associated with A1 while the 17 km/s feature is either close to A2 for the model assumed, or alternatively along the possible ridge joining the positions A1 and A2. It would appear that these components are associated with the regions of comparatively high density which in addition appear also to be regions of comparatively high internal velocity. But this is probably not unique to the source W49 and in fact the source of OH in Sagittarius is in a correspondingly high density region<sup>11</sup>, as is the source W3C, while the emission peaks of OH in NGC 6334 appear to be associated with the edge of comparatively bright optical emission regions<sup>4</sup>, which probably have high expansion velocities.

The indication that OH emission is associated with areas of  $\text{H II}$  regions of comparatively high density is not inconsistent with previous theories. But on the other hand it also raises the possibility that a further mechanism may be taking place. Recent observations in the laboratory by Spindler *et al.*<sup>11</sup> have shown that OH may be formed in an electronically excited state as a two-body process involving atomic oxygen and hydrogen. Such a reaction could be a competing mechanism in dense regions and is well worth consideration.

This work was carried out under an operating grant from the National Research Council of Canada, to whom one of us (R. B.) is also grateful for a graduate research fellowship.

### Mechanism for Anomalous OH Emission from $\text{H II}$ Regions

SEVERAL suggestions have been made to explain the formation of OH in the galaxy, together with possible pumping mechanisms to produce the laser action considered responsible for high anomalous brightness temperatures at least as high as  $10^{10} \text{ }^\circ\text{K}$  (ref. 1). It is usually assumed that OH is produced in the presence of interstellar particles

by sputtering or by a process of chemical exchange on the particles; they also act as the third body and help to conserve energy and momentum. The pumping mechanism suggested by Litvak *et al.*<sup>2</sup> is by continuum ultra-violet radiation which induces selective transitions from the various rotational levels of the ( $X^2\Pi$ ) ground state to the ( $A^2\Sigma$ ) electronic excited state. By this means an inversion of the population of the ground doublet state is obtained, but on the other hand the energies involved are close to the dissociation energy for OH. The analysis by Cook<sup>3</sup> invokes pumping by Lyman- $\alpha$  radiation, but again the energy involved is more than twice the dissociation energy and it is likely that a large percentage of the OH would be dissociated. The two-body process proposed by Symonds<sup>4</sup> of forming excited OH from O- and H+ could possibly also provide the pumping mechanism, but unfortunately it requires the liberation of a large amount of energy and it seems unlikely that this process would be effective. A more interesting mechanism has recently come to light with the observation in the laboratory by Spindler *et al.*<sup>5</sup> of the formation of OH in an electronically excited state, as a two-body process involving atomic oxygen and hydrogen, with the emission of radiation in the 3064 Å band. The rate for the reaction has been determined<sup>6</sup>, and can be expressed by

$$I = K[\text{H}][\text{O}] \text{ photons cm}^{-3} \text{ sec}^{-1}$$

where  $I$ , the intensity of the emission, is assumed equal to the rate of formation of OH molecules,  $[\text{H}]$  and  $[\text{O}]$  are the densities of atomic hydrogen and oxygen respectively, and  $K = 3 \times 10^{-21} \text{ molecules cm}^{-3} \text{ sec}^{-1}$  is the rate constant at room temperature. Because this reaction could well be taking place in the cooler parts surrounding individual  $\text{H II}$  regions it is of interest to assess the possibility that it is also the cause of anomalous OH emission.

A realistic region for OH formation is in the pressure wave immediately ahead of a  $D$ -type ionization front. Kaplan<sup>7</sup> has shown that the density here can rise to about forty times the mean density and the temperature increase to a value of about  $1,000^\circ \text{K}$  in comparison with the  $100^\circ \text{K}$  for the neutral gas. The width of the front is of the order of  $10^{-2} \text{ pc}$ . The  $D$ -type front is the most likely<sup>8</sup>, provided that the gas density is greater than about  $100 \text{ cm}^{-3}$ . Further indications that such a region may be responsible can be seen from observations on NGC 6334 where the OH emission arises at the edge of bright optical emission regions<sup>9</sup>. In general the observed Doppler shifts are consistent with this hypothesis. If we take a previously derived model for W49 (ref. 10) where densities of at least  $10^4 \text{ cm}^{-3}$  can exist in the  $\text{H II}$  regions, the corresponding density of hydrogen in the pressure wave will be about  $4 \times 10^5 \text{ atoms cm}^{-3}$  and, taking the normal cosmic abundance, the density of oxygen will be  $4 \times 10^2 \text{ cm}^{-3}$ . Assuming that the rate constant is proportional to temperature<sup>2</sup>, then the rate of formation of excited OH will be about  $10^{-12} \text{ molecules cm}^{-3} \text{ sec}^{-1}$ . The molecules are formed in a fairly high rotational level of the  $A$ -state, and the way in which the molecule reverts to the ground state requires detailed calculations. Collisions during the lifetime of the  $A$ -state (about  $10^{-6} \text{ sec}$ ) could induce transitions down the vibrational-rotational levels before the transition to the  $X$ -state. Alternatively, the initial transition could be to a high rotational level of the  $X$ -state followed by transitions down to the ground state. In either case it is possible that selection rules could produce an inversion of the population of the relevant ground state  $A$ -doublet level. Transition probabilities have not yet been calculated, but it is possible to obtain the order of magnitude required. The lifetime of the hyperfine  $A$ -doublet states is long in comparison with the lifetime of the other states and amounts to about  $10^{11} \text{ sec}$ . During this time  $10^{-1} \text{ OH molecules cm}^{-3}$  will be formed. Because the required population inversion assumed necessary for laser amplification is about  $10^{-5} \text{ cm}^{-3}$  (ref. 11), if the difference in the resulting transition rates to the upper and lower states amounts to

only  $10^{-4}$ , this would be sufficient. More detailed calculations show that the rates of formation for the proposed mechanism are too small for the intensity to be produced entirely in the pressure wave, but rather that the pressure wave is a region of amplification of the radiation from a source situated behind it. The recent observations<sup>1</sup> that the source of emission can have dimensions as small as  $10^{-4}$  pc., however, supports this suggestion.

The further complication that the observed emission shows very high percentage polarization has not been considered, but it might be mentioned that the parts of an HII region which are most likely to have comparatively large values for the magnetic field are those immediately in front of a moving ionization front. Though the mechanism is still somewhat speculative, it is by no means more so than the other proposals.

The suggested mechanism has the additional attraction that it may be amenable to observation. The transition to the ground state corresponds to emission in the 3064 Å wavelength band, and the brightness of the emission from an average HII region should amount to about  $10^6$ – $10^7$  photons  $\text{cm}^{-2}$ . This should be observable from those HII regions that can be seen optically. Unfortunately, the atmospheric extinction is high at these wavelengths and observations from near the ground may be confused by the presence of atmospheric OH. It should, however, be a suitable observation to make from space vehicles.

This work was carried out under an operating grant from the National Research Council of Canada.

We thank Dr D. B. McLay and the members of the Department of Natural Sciences at York University, Toronto, for many helpful discussions on the spectrum of OH.

### Critique of the "Clark Effect"

A DIRECT measurement of the magnetic field strengths within the Galaxy would be of the greatest importance for understanding its structure and evolution<sup>1</sup>, and Clark<sup>2</sup> has proposed a method based on the effect of a magnetic field on the anomalous dispersion of 21 cm radiation passing through neutral hydrogen. I wish to point out that Clark's calculation contains a fundamental error, rendering the method much less effective than he claims.

Clark's method makes use of the fact that the right-handed and left-handed circularly polarized components of 21 cm radiation have different indexes of refraction in hydrogen gas embedded in a magnetic field, as a result of the different effects of the 1s triplet excited states on the resonant forward scattering. Feynman diagrams for the two important scattering processes are shown in Fig. 1. Fig. 1A represents scattering from the ground state. Clark's principal error was to neglect the process represented by Fig. 1B—induced scattering from an excited state. Its contribution to the index of refraction is of opposite sign.

Fig. 1. Feynman diagrams of the two scattering processes which contribute to the index of refraction. The heavy line represents the 1s singlet ground state of hydrogen, while the double line represents one of the 1s triplet excited states. Only the induced emission should be included in B.

Although the correct result may be obtained entirely through the use of the optical theorem<sup>3</sup> modified by the possibility of induced emission, the simplest approach is the use of the Kramers–Kronig dispersion relation<sup>4,5</sup>, which applies quite generally to any scattering process. For each component  $i$  of polarization, this relates the phase shift  $d\varphi_i$  relative to propagation in a vacuum to the optical depth  $d\tau_i$  along a path length  $dl$  at frequency  $\nu$  by

$$d\varphi_i(\nu) = \frac{1}{2\pi} P \int_0^\infty \frac{d\tau_i(\nu')}{\nu' - \nu} d\nu' \quad (1)$$

near resonance, where  $P$  denotes the Cauchy principal value.

In order to relate the Faraday rotation  $\psi$  of the plane of polarization, which is half (Clark used 1) the difference in phase between the right-handed and left-handed circularly polarized components, to the observed total optical depth  $\tau$ , we need the explicit expression for the optical depth for each polarization. This is

$$d\tau_i = \frac{\pi^2 e^2 \hbar \nu dl}{4m^2 c^3} \{ 2 \sin^2 \theta [n_g^{(0)}(\nu) - n_0(\nu)] + (1 \mp \cos \theta)^2 [n_g^{(+)}(\nu) - n_+(\nu)] + (1 \pm \cos \theta)^2 [n_g^{(-)}(\nu) - n_-(\nu)] \} \quad (2)$$

in the limit of vanishing natural widths of the states, which is certainly justified in this case. Here  $\theta$  is the angle between the ambient magnetic field and the propagation direction,  $n_j(\nu) d\nu$  is the number density of hydrogen atoms in excited state  $j$  which can resonantly emit a photon received in the frequency range  $\nu$  to  $\nu + d\nu$ , and  $n_g^{(j)}(\nu) d\nu$  is the same for absorption by a ground state atom into excited state  $j$ . The resonant frequencies are  $\nu_0 = 1.42 \times 10^9$  c/s and  $\nu_{\pm} = \nu_0 \pm 0.5 \Delta\nu$  with  $\Delta\nu = 2.80 \times 10^6 H_0$  c/s, where  $H_0$  is the strength of the magnetic field in gauss. Because

$$\tau_r - \tau_l = \frac{\pi^2 e^2 \hbar \nu}{m^2 c^3} \int \{ [n_g^{(-)}(\nu) - n_-(\nu)] - [n_g^{(+)}(\nu) - n_+(\nu)] \} \cos \theta dl \quad (3)$$

$$\tau \cong \frac{\tau_r + \tau_l}{2} \cong \frac{\pi^2 e^2 \hbar \nu}{m^2 c^3} \int [n_g^{(j)}(\nu) - n_j(\nu)] dl \quad (4)$$

we obtain

$$\tau_r - \tau_l \cong \frac{d\tau}{d\nu} \Delta\nu \cos \theta \quad (5)$$

where we have used the fact that under all astrophysical conditions the four states in question are almost equally populated. Using equations (1) and (5), we obtain for the Faraday rotation

$$\psi(v) = 0.5 (\varphi_r - \varphi_l) = \frac{\Delta v \cos \theta}{4\pi} P \int_0^\infty \left( \frac{1}{v' - v} \right) \frac{d\tau}{dv} (v') dv' \quad (6)$$

$\psi$  is positive in the clockwise direction when looking into the wave.

If one neglects the removal of the derivative to outside the integral in Clark's result, then the ratio of equation (6) to his formula is  $(0.5)(2\pi\hbar v/kT_s) \cos \theta$  (after correction of some numerical errors in Clark's computation), where  $T_s$  is the spin temperature of the hydrogen gas. The second factor,  $0.0681/T_s$ , is just the fractional difference in population of the ground and excited levels, and indicates the reduction in the net phase shift due to the induced scattering. Because typically  $10^3 \leq T_s \leq 10^4$  °K, the effect will be much smaller than Clark claims. In fact, for an absorption profile  $\tau(v) = \tau_0 \exp [-(v - v_m)^2/v_v^2]$ ,

$$\psi(v_m) = - \frac{\tau_0 \cos \theta \Delta v}{2 \sqrt{(\pi) v_v}} \text{ radians} \quad (7)$$

and in general,  $|\psi| \sim 0.3 \tau \Delta v/W$ , where  $W$  is the width of the feature. Because for HI clouds,  $W \sim 10^4$  c/s, the rotation will usually be very small.

I thank R. P. Feynman for a helpful discussion. This work was supported in part by the US National Science Foundation and the US Office of Naval Research.

## PLANETARY SCIENCE

### Isolating Lunar Materials

MEMBERS of the Surveyor scientific evaluation and analysis team have shown, by counts of particles on Surveyor I and III photographs of the lunar terrain, that at two places in Oceanus Procellarum the surface rock is particulate with grain sizes down to less than 1 mm in diameter. Laboratory studies recently undertaken by the lunar team of the University of London Observatory point to a new method of investigating the sizes of submillimetric particles on the Moon. Instead of concentrating on only one of the possible physical methods—such as albedo measurements, spectrophotometry and polarization, taken separately—of probing the nature of the surface of the Moon, we integrate these approaches to draw conclusions about the nature of the lunar material only after the requirements of all avenues have been satisfied. In this way, many materials may be eliminated from candidature for the lunar surface and the choice of possible material suffers stricter control. The method may be illustrated by reference to certain physical studies of eleven basic and intermediate rocks ground to various grain sizes.

Eleven Hawaiian rock specimens (listed in Table 1) were prepared in four ranges of grain size centring on 160 $\mu$ ,

83 $\mu$ , 62 $\mu$  and 26 $\mu$ , respectively. Of these, the specimens GF/H/u9 and GF/H/u2 were processed from the original specimens GF/H/9 and GF/H/2 by melting them in a furnace and upwelling them in a vacuum chamber to simulate the formation of lunar lavas<sup>1</sup>. The diffuse normal albedos of the forty-four powdered samples were measured as a function of wavelength in the interval 3750–7200 Å using a Beckmann mark II ratio recording spectrophotometer.

The colour excess,  $E$ , was derived from the records by means of the relation

$$E = 2.5 \log (J_V/J_B) + 0.09 \quad (1)$$

where  $J_V$ ,  $J_B$  are the observed  $V$  and  $B$  fluxes from the powders. It was found that, for all the cases,

$$G \approx CA^{-2} \quad (2)$$

where  $G$  is the grain size in  $\mu$ ,  $A$  is the albedo expressed as a percentage at 5600 Å and  $C$  is a parameter that increases with the mean colour excess of a group of rocks, as indicated in Table 1.

Table 1

Rock powder	Group	Log $C$	Mean $E$
GF/H/u9 Basalt glass	1	3.25	-0.01 (bluer)
u2 Basalt glass			
3 Non-porphyrritic basalt			
9 Basalt	2	3.75	+0.05
10 Basalt			
1 Basalt			
8 Ankaramite			
2 Felspathic olivine basalt	3	4.14	+0.08
11 Hawaiite			
4 Picrite basalt	4	4.62	+0.27 (redder)
7 Trachyte			

This means that, for a given albedo, the redder rocks must in general have larger grains than bluer rocks. For a particular rock, however, the redness increases with decreasing grain size. This is not true for rocks of the higher groups (3 and 4 in Table 1), which have comparatively high albedos for a given particle size; for these rocks the colour excess shows no clear dependence on grain size. This is probably because colour is controlled, in these instances, largely by external reflexion from facets rather than by transmission through and absorption and internal reflexion in grains.

Sytinskaya<sup>2</sup> pointed out the apparently special location of the lunar domain on a plot of colour excess against albedo. Extending this work, Fielder *et al.*<sup>3</sup> found several powders which, in their natural, non-irradiated state, did in fact intrude into the lunar domain. The number of powders matching the Moon in this way may be enlarged further using equation (2) together with the relation (extrapolated where feasible) between grain size and colour excess. (For groups 1 and 2, the relation between  $E$  and  $\log G$  is linear.) Taking  $\log A$  for the Moon to range from 0.7 to 1.23 and  $E$  for the Moon, from +0.09 to +0.45, after Sytinskaya<sup>2</sup>, the relations exclude three of the powders in Table 1 and attribute certain ranges of possible grain sizes,  $G_{A,E}$ , to the others. Thus the range  $G_{A,E}$ , listed in Table 2, states the condition that the named powders are included in the lunar domain of the  $A-E$  diagram.

Dr A. Dollfus is collaborating with us in an extensive polarization research programme in which the same rocks are used. E. L. G. Bowell, who is working with Dollfus, told us that he has shown that the parameters  $G$ ,  $A$  and  $P_m$ —the maximum positive value of the polarization—are mutually dependent. Furthermore, he showed that, by comparison with the lunar data, polarization data on rock powders, including those in Table 1, argued for a lunar grain size of about 20 $\mu$ . Clearly, the 20 $\mu$  particles required to produce the polarizing properties of the Moon must be scattered over, or mixed with, the larger particles recorded by the lunar probes. Taking all these facts

Table 2	
Rock powder	$G_{A.F.}(\mu)$
$GF/H/u9$	15-53
$u2$	<16
3	<19
9	<18
1	16-40
8	19-141
4	44-178
7	>186

into account therefore those of the rocks in Table 2 which are most likely to have the characteristics of the lunar surface are  $GF/H/u9$ , 1 and 8. The trachyte  $GF/H/7$  certainly would not polarize light like the Moon.

It will be seen that this preliminary study—which is intended to be illustrative only—describes a new method of narrowing the choice of lunar surface materials through an examination of the albedo, colour and polarization properties of sub-millimetric particles as a function of grain size. Contrary to earlier findings, certain rocks in their natural, non-irradiated state are evidently possible candidates for a lunar surface model.

This research was financed through a research grant from NERC. I thank Drs G. P. Kuiper and H. A. Powers for making collection of the rocks in Hawaii possible, Dr M. K. Wells for examining and describing thin sections of the rocks prior to their being pulverized, Dr K. H. Ruddock for access to the spectrophotometer, Mrs M. Stearman for measuring the albedos and colour excesses, and Mr L. Wilson for computing assistance. I also thank Mr. E. L. G. Bowell for making his paper available to me before publication and Dr J. E. Guest for useful discussions.

### Serpentine Dehydration Curves and their Bearing on Serpentine Deformation in Orogenesis

SERPENTINITE bodies characteristically occur in regions that have undergone an orogenesis of alpine type<sup>1</sup>. The more recent recognition that significant quantities of serpentinites are associated with the oceanic crust, oceanic trenches and mid-oceanic ridges<sup>2</sup> extends the possible role of serpentinites in tectonic processes which involve the crust and upper mantle. Thus the experimental deformation of serpentinite at high pressures and temperatures<sup>3</sup> has important implications for theories of the tectonic emplacement of serpentinites and principal tectonic processes such as mountain building. Raleigh and Paterson<sup>3</sup> have found that at low temperatures and high pressures serpentine has strength comparable with granite. With an increase in temperature sealed specimens showed marked weakening accompanied by the development of brittleness.

Results<sup>3</sup> for two serpentinites are shown in Fig. 1; the Fidalgo Island serpentinite contains brucite while the Tumut Pond serpentinite does not. Raleigh and Paterson attribute the weakening and embrittlement of the serpentinite to dehydration and suggest that the pore pressure of the liberated water reduced the effective confining pressure. They remark that the temperature at which the serpentinite bearing brucite is weakened does not coincide well with the phase equilibrium data, and that much more detailed phase equilibrium studies may be required.

Bowen and Tuttle<sup>4</sup> have put forward two reactions for the dehydration of serpentine

Fig. 1. Reaction curves for the dehydration of serpentine compared with previously reported curves. The conditions of weakening of deformed serpentinites are also shown. Reaction (1):  $\times$ — $\times$ ; reaction (2):  $\bullet$ — $\bullet$ . Numbers refer to: 1, Pistorius; 2, Kitahara *et al.*; 3, Yoder; 4, Bowen and Tuttle; 5, this work; 6, Raleigh and Paterson.

Fig. 1 compares the reaction curves of the two, measured to 3 kbars including the results of more recent experiments<sup>5,6</sup> in the 6–40 kbar pressure range. These show a reasonable fit with the low pressure results of Bowen and Tuttle, although the results of Pistorius<sup>5</sup> for reaction (2) can be extrapolated to somewhat lower temperatures. Yoder's<sup>7</sup> "preliminary unreversed curve" for (1) extends to lower pressures and it lies at slightly lower temperatures than the other determinations. No other detailed studies of these reaction curves below 5 kbars appear to have been published, despite their significance and despite the known problems of metastability in this system<sup>8,9</sup>.

We have undertaken a study of serpentine stability in the system  $\text{MgO}-\text{FeO}-\text{Fe}_2\text{O}_3-\text{SiO}_2-\text{H}_2\text{O}$  in which the oxygen fugacities have been buffered; particular attention being paid to the attainment of equilibrium and to the reversal of reactions<sup>10</sup>. By duplicating experiments, we are confident that the reaction curves presented by Bowen and Tuttle for serpentine free of iron are too high in temperature because metastable products are produced from oxide starting mixtures in short duration runs (3 days). Longer runs, and the use of starting mixtures composed of synthetic minerals involved in the reactions, provide the revised results shown in Fig. 1. Complete reaction was not achieved at temperatures within 50° C of the curves even after runs of 25 days' duration. Each run compared reactions in separate starting mixtures corresponding, respectively, to the phase assemblages stable above and below a reaction curve. The position of the revised curve for reaction (1) is based on recognition of the direction of reaction—hydration or dehydration—in these starting mixtures; the horizontal lines on the curve represent the experimental temperature bracket. A theoretical curve for reaction (1) calculated from new thermochemical data on forsterite and serpentine<sup>11</sup> shows very good agreement with our experimental curve. The arrow on the curve for reaction (2) indicates that its position has been determined so far only on the basis of the reverse hydration reaction. The precise position of the equilibrium curve for reaction (2) is not yet known because partial dehydration occurs in many samples held below the plotted curve for as long as 3 weeks.

Reaction (2) is lowered by about 100° C compared with previous results, bringing it much closer to the temperature of weakening of the Fidalgo Island serpentinite bearing brucite. Reaction (1) is lowered by 40°–70° C compared with the original curve of Bowen and Tuttle, which moves the dehydration to temperatures lower than that of weakening of the Tumut Pond serpentinite free of brucite. The deformation experiments, however, were of short

duration<sup>3</sup> and the previous phase equilibrium results shown in Fig. 1 confirm that with shorter runs the dehydration occurs at higher temperatures than the equilibrium reaction.

The results of these phase equilibrium experiments are consistent with the proposal of Raleigh and Paterson that the weakening of serpentinite is caused by liberation of water during dehydration, which suggests that the presence of brucite is probably responsible for the low temperature weakening of the Fidalgo Island serpentinite. Thus the presence or absence of brucite in serpentinite<sup>12</sup> may provide an important control on the various tectonic processes discussed by Raleigh and Paterson.

### Potassium-Argon Ages from the Oldest Metamorphic Belt in India

INTENSIVE structural and stratigraphic studies, supplemented by several potassium-argon ages, recently led Sarkar and Saha<sup>1-3</sup> to recognize two distinct orogenic belts in the Pre-Cambrian tract of Singhbhum and adjacent areas<sup>4,5</sup> in Eastern India (Fig. 1, inset). The orogeny which gave rise to the Iron Ore orogenic belt in the south—which includes the Iron Ore Series of low grade metasediments and metavolcanics—had its culmination in the emplacement of the granitic rocks (about  $2,000 \times 10^6$  yr) which constitute the northern part of the Singhbhum granitic complex (Fig. 1). The Singhbhum Orogenic belt in the north, which is thought to have a closing age of about  $900 \times 10^6$  yr and which consists mostly of high grade metasediments and basic rocks, truncates the Iron Ore Orogenic belt along a prominent arcuate thrust zone. Evidence for the existence of an older group—underlying the Iron Ore Series, the Older Metamorphic Series—of moderate to high grade metamorphic argillites, calc-magnesian metasediments and arenites was also recorded<sup>2,3</sup>. Sarkar and Saha<sup>6</sup> also suggested that there was old granitic activity associated with the Older Metamorphic Series about  $3,000 \times 10^6$  yr ago on the basis of a potassium-argon age of  $3,035 \times 10^6$  yr (ref. 7) from a coarse muscovite pegmatite near Joropokhar ( $22^\circ 24' 45''$ :  $85^\circ 45' 10''$ ).

The area of fifty square miles to the west and south of Champua ( $22^\circ 04'$ :  $85^\circ 40'$ ) (Fig. 1) constitutes the type area of the Older Metamorphic Series; there the series is extensively injected and replaced by granite and pegmatite<sup>4,8</sup>. In an attempt to establish the stratigraphic status of the Older Metamorphic Series more firmly the type area

of Older Metamorphics and adjacent Singhbhum granitic complex around Champua (Fig. 1) was selected for intensive structural, petrological<sup>9</sup> and geochronological studies.

An important unit of calc-magnesian metamorphic rocks which outcrops throughout Champua is folded into a megascopic, almost neutral fold plunging steeply E.N.E.; mica schists lie along the core and flanks of this major fold. The prominent bedding foliation ( $S_1$ ) in these rocks and the puckers and mineral lineations ( $L_1$ ) (which are subparallel to the principal fold axis) appear to be continuous and conformable with the gneissose foliation and mineral lineations in the adjacent biotite granodiorite gneiss. In both the metamorphics and the gneiss  $S_1$  has been locally folded megascopically and mesoscopically about moderate to steep S.E. plunging axes and a second foliation ( $S_2$ ) has developed along the axial planes of such folds (Fig. 1). Towards the north, the Older Metamorphics are overlain unconformably by a group of slightly metamorphosed basic lavas (Jagannathpur lavas)<sup>10-12</sup> which dip gently to the west.

The principal mineral assemblages of the Older Metamorphic Series are plagioclase-hornblende-diopside-calcite-quartz-(sphene), plagioclase-hornblende-biotite-calcite-quartz, plagioclase-hornblende-diopside-quartz-epidote, plagioclase-hornblende-chlorite-calcite-(magnetite); quartz-muscovite-biotite-magnetite and quartz-muscovite-(oligoclase). The mineral assemblage suggests a sillimanite almandine sub-facies of the amphibolite facies with partial retrogression to staurolite almandine sub-facies<sup>13</sup>. The small intrusions of non-foliated metabasalt (plagioclase-hornblende-chlorite-biotite-iron ore-quartz-augite) within the calc-magnesian metasediments show a much lower grade of metamorphism (greenschist facies) and appear to have been emplaced subsequent to the chief regional metamorphism (and granitization) of the Older Metamorphics.

The biotite granodiorite gneisses of the area are medium grained, well foliated rocks which consist dominantly of plagioclase ( $An_{24-40}$ ) and quartz, together with fair amounts of biotite, occasional microcline, chlorite, epidote, hornblende sphene and rare muscovite. The average mineral composition (by weight per cent) of these granitic rocks (based on twenty-four analyses) is quartz, 21.6; plagioclase, 65.2; microcline, 3.6; colour index, 9.4 (including 6 per cent biotite). A distinct gradation can be seen from the biotite granodiorite to the calc-magnesian metasediments (through an intermediate stage of hornblende granodiorite) around many inclusions in the metamorphics; clear textural evidence of replacement of the hornblende-epidote aggregate by the later formed plagioclase-quartz is common. These facts, taken together with the evidence of structural unity between the granitic and the metamorphic rocks, suggest a metasomatic transformation of the calc-magnesian metasediments (and meta-argillites) to biotite granodiorite-gneiss, and that  $S_1$  and  $L_1$  of the granodiorite gneiss are relics. Sericitization along the  $S_2$  plane of the gneiss suggests that the granitization occurred after the development of  $S_1$ , but before the second folding.

For the purpose of age determination eight representative samples were collected by A. K. Saha and B. Chakravarti from the Older Metamorphics of Champua area. The mineral samples (two of muscovite from mica schists, three of hornblende from calc-magnesian metasediments and three of biotite from biotite granodiorite gneisses) were prepared from the rocks by grinding and sieving; biotite and hornblende were separated electromagnetically and muscovite by inclined shaking board method. The separated mineral samples were dated by S. N. Sarkar and J. A. Miller, using potassium-argon<sup>14,15</sup>. Potassium oxide content was determined by flame photometry; up to six separate portions of each sample were measured and the mean value and error calculated from the standard deviation of the mean of the measurements (Table 1). To avoid any systematic error in this method, checks against

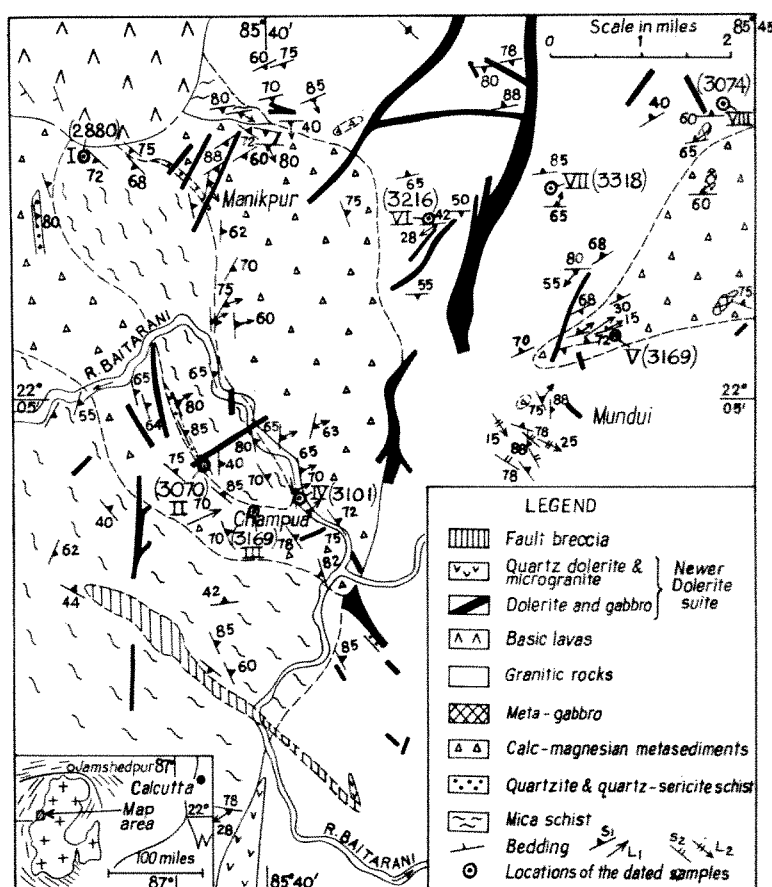

Fig. 1.

standard samples were carried out. The  $^{40}\text{Ar}$  content was determined using the isotope dilution technique. From the  $^{36}\text{Ar}$ ,  $^{38}\text{Ar}$  and  $^{40}\text{Ar}$  ratios (measured with Omegatron type mass spectrometer)<sup>16</sup> the percentage of  $^{40}\text{Ar}$  of atmospheric origin and the volume of radiogenic  $^{40}\text{Ar}$  of sample were calculated. The total error in age determination of each sample was calculated on the basis of observed errors in multiple potassium oxide determinations, the isotopic composition and volume of  $^{38}\text{Ar}$  spike and the isotopic ratios of the final gas mixture. The age data are given in Table 1, and location and petrographic description of the samples in Table 2.

Sericitized muscovites (Table 1 and Fig. 1) from mica schists yielded ages of  $2,880$  and  $3,070 \times 10^6$  yr, three hornblende samples from calc-magnesian metasediments yielded ages of  $3,169$ ,  $3,101$  and  $3,169 \times 10^6$  yr, whereas three biotite samples from biotite granodiorite gneiss gave ages of  $3,216$ ,  $3,318$  and  $3,074 \times 10^6$  yr. Sample 1 (muscovite) is situated about 250 m south of the boundary of the overlying gently dipping younger Jagannathpur lavas, the base of which was less than 50 m above the sample locality before erosion. The relatively low apparent age ( $2,880 \times 10^6$  yr) of the sample may be due to partial

argon loss from the finely divided sericite as a result of heating by the lava.

Thus, with the exception of sample 1, seven samples of three different minerals—muscovite, hornblende and biotite—from parametamorphics and granite gneisses yield fairly concordant potassium-argon ages ranging between  $3,070$  and  $3,318 \times 10^6$  yr. This suggests one chief metamorphic episode in the Champua rocks. As individual dates indicate the time at which metamorphism and/or granitization ended, it may be concluded on the basis of available data that regional metamorphism and granitization of the Older Metamorphic Series must have closed within the period  $3,318$ – $3,070 \times 10^6$  yr. Because these rocks are surrounded on three sides by the younger Singhbhum granite complex, parts of the Older Metamorphics area might have been reheated (probably causing partial argon loss) during the emplacement of the vast volumes of Singhbhum granite magmas in the adjacent areas. Because the average of seven dates is  $3,159 \times 10^6$  yr and there is the possibility of partial argon loss due to later thermal events, the closing date of the Older Metamorphic Cycle may be taken as about  $3,200 \times 10^6$  yr; the actual deposition of the sediments on an older basement

Table 2. SAMPLE LOCALITIES AND DESCRIPTIONS

A brief description of each mineral sample and the host rock from the Older Metamorphic Series is given in the following order: locality and sample numbers, type of mineral and rock, location in latitudes and longitudes, petrographic description.

I. J/10/62. Partly sericitized muscovite from muscovite-quartz-plagioclase schist ( $22^{\circ} 7' 20''$  N. :  $85^{\circ} 38'$  E.) from stream section west of Daobera, near the boundary of the overlying basic lava. Subidioblastic muscovite flakes (0.5–2.0 mm) with preferred dimensional orientation define foliation. In patches they are altered to aggregates of finely divided sericite showing subparallel arrangement. Inequant plagioclase (oligoclase) and quartz (<1 mm) are often elongated subparallel to foliation. Reddish brown and opaque dusty iron ore as accessories.

II. AK/28-I. Sericitized muscovite from muscovite-quartz-plagioclase (—rutile) schist ( $22^{\circ} 4' 15''$  N. :  $85^{\circ} 39' 15''$  E.) from 1 mile north-west of Champua. Subidioblastic muscovite flakes (0.3–5 mm) occur mostly as relicts in the groundmass of fine acicular aggregates of sericite, individual needles (0.05–0.2 mm). Slightly elongated quartz grains (0.2–1.0 mm) are subparallel to foliation defined by preferred orientation of muscovite and sericite. Coarse quartz (<0.9 mm) occur in pods. Inequant grains of plagioclase (0.2–0.4 mm) are partly altered to sericite aggregates.

III. AK/75. Hornblende from hornblende-plagioclase-quartz schist ( $22^{\circ} 4' 40''$  N. :  $85^{\circ} 40'$  E.), north-west of Champua. Fine grained well foliated rock with fairly elongated subidioblastic hornblende (0.1–1.0 mm), subequant grains of moderately saussuritized plagioclase (0.2–1.0 mm), few xenoblastic quartz (0.1–0.2 mm), sphene and iron ore. Hornblende, 56.2; plagioclase, 38.2; quartz, 5.0; sphene, 0.3 and iron ore, 0.3, weight per cent.

IV. C/1/63. Hornblende from hornblende-plagioclase-quartz schist ( $22^{\circ} 4' 40''$  N. :  $85^{\circ} 40' 20''$  E.), north-east of Champua. A large number of granitic injections occur within 100 yd. of this exposure. Nematoblastic texture, about 70 per cent xenoblastic to subidioblastic elongated hornblende (0.1–1.5 mm), which is pleochroic (pale to dark green) and shows preferred orientation; xenoblastic aggregate of saussuritized plagioclase and quartz (0.1–0.2 mm) with little biotite, calcite, sphene and iron ore.

V. AK/102. Hornblende from hornblende-plagioclase-quartz schist ( $22^{\circ} 5' 45''$  N. :  $85^{\circ} 43' 30''$  E.) from north of Mundui. Coarse granoblastic texture with subidioblastic hornblende (0.2–2.0 mm) (pleochroic from pale green to brownish green), with a little xenoblastic quartz and saussuritized plagioclase (0.2–0.4 mm). Sphene, apatite and dusty ore as accessories. Hornblende, 75.8; plagioclase, 21.3; quartz, 2.6 and sphene, 0.2 weight per cent.

VI. AK/109. Biotite from biotite granodiorite gneiss which is metamorphically granitized hornblende schist ( $22^{\circ} 7' : 85^{\circ} 41' 50''$ ) from north of Pata Joint. Rudely foliated rock with subidioblastic biotite flakes (<2 mm) (pleochroic pale yellow to dark greenish brown and brown), a few flakes partly altered to chlorite along cleavage; hornblende in xenoblastic or skeletal grains (<2 mm) (pleochroic pale yellow to dark green). Xenoblastic plagioclase, quartz, microcline (<5 mm) and myrmekite. Sphene, epidote, apatite and opaque minerals as accessories. Quartz, 22.6; microcline, 2.7; plagioclase, 64.7; biotite, 6.1; hornblende, 0.3; opaque minerals, 1.0 and others, 2.5, weight per cent.

VII. AK/214. Biotite from biotite granodiorite gneiss ( $22^{\circ} 7' 45''$  N. :  $85^{\circ} 43'$  E.) from granitized schist 1.5 miles north-east of Pata Joint. Well foliated rudely banded rock with quartz (0.8–2.5 mm), slightly saussuritized oligoclase-andesine (1.5–2.0 mm), tabular biotite (0.5–1.5 mm), some chlorite (<0.3 mm) in the matrix associated with biotite, sphene (<0.4 mm) and interstitial microcline.

VIII. AK/161. Biotite from biotite granodiorite gneiss ( $22^{\circ} 8' 45''$  N. :  $85^{\circ} 44' 40''$  E.), from granitized schist east of Gangpur. Well foliated, subequigranular rock with quartz (0.4–0.6 mm), moderately saussuritized acid andesine (0.7–1.5 mm), tabular biotite (0.3–1.0 mm), interstitial microcline in small grains, flakes of chlorite (<0.3 mm) intergrown with biotite, sphene and iron ore (<0.2 mm).

and their metamorphism must have taken place much earlier than about  $3,300 \times 10^6$  yr.

Although the actual extent of the rocks representative of this cycle is not fully known at present, the recent field studies by A. K. Saha and his co-workers suggest that a considerable part of the younger Singhbhum granitic complex between longitudes  $22^{\circ} 15'$  E. and  $21^{\circ} 45'$  E. has relicts of rocks belonging to the Older Metamorphic Cycle.

On the basis of all the available age data<sup>6,7,17–19</sup> from the Indian Shield it may be concluded that the Older Metamorphics of Singhbhum-Keonjhar represent relicts of the oldest recognizable orogenic belt in India. This cycle may be correlated with the Katarachean cycle ( $3,500$ – $3,000 \times 10^6$  yr) of the Baltic Shield<sup>20</sup> where Katarachean rocks occur as relicts in the younger Saamian granites and gneisses of the Kola Peninsula. Radiometric ages above  $3,000 \times 10^6$  yr are rather rare and a few reported from Africa<sup>21</sup> are a model age of galena (about  $3,480 \times 10^6$  yr), Bomu Complex, North Congo, a strontium-rubidium age of microcline ( $3,270 \times 10^6$  yr) from Upper Luanyi Cycle pegmatite, South Congo, and a potassium-argon age of biotite ( $3,150 \times 10^6$  yr) from granite at Broderick Falls, Kenya. Two anomalously high potassium-argon ages ( $3,300$  and  $3,700 \times 10^6$  yr) from biotite near the Grenville front in East Canada, where co-existing minerals yielded much younger ages, are thought to reflect<sup>22</sup> the excess argon content of the mineral rather than a relict of an older orogenic belt.

We thank Mr B. Chakravarti for field and petrographic data and for samples, Mr K. Pal and Mr M. Prakash for assistance with mineral separation, and Dr R. L. Grasty for some argon determinations. We also thank the Nuffield Foundation for support.

## Isotopic Ages from the Pegmatite Provinces of Eastern Brazil

EASTERN Brazil is composed mainly of metamorphosed basement rocks<sup>1</sup>, gneisses and paragneisses (Fig. 1), which are found to increase in grade of metamorphism towards the coast, reaching granulite facies around Juiz de Fora and Lima Duarte, but which at the same time decrease in intensity of tectonic deformation. The region has been affected by at least two orogenic episodes each accompanied by characteristic igneous activity. Traces of a third earlier orogeny occur, but the first distinct evidence of movement is that of the Barbacena orogeny with its quartz dioritic type of intrusions. This is followed later by the Paraíba or Algonkian orogeny with its granitic intrusions, rich in alkali feldspar<sup>2</sup>.

The basement gneisses are cut by coarse pegmatite veins which are intruded as part of the late stage igneous activity associated with the orogenies. Samples of micas were collected from the pegmatites by one of us (H. E.) and sent to Cambridge for potassium-argon analysis. The potassium content of the samples was measured on an EEL flame photometer and the argon isotope ratios on an omegatron<sup>3,4</sup> (Table 1).

Six of the nine samples analysed gave ages of around  $550$ – $500 \times 10^6$  yr. Loss of argon, probably resulting from secondary alteration, may account for the younger age of sample SA 164. The high age of the biotite from the Socorro pegmatite may have been caused by incomplete

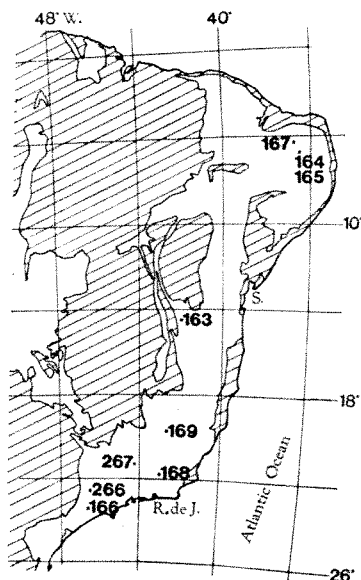

Fig. 1.

out-gassing during the Paraíba orogeny, but is more likely to be because the pegmatite was syntectonic.

These ages may be assumed to correspond to the time of intrusion of the pegmatites, although they do in fact refer to the time when the minerals had cooled sufficiently to become closed systems and trap the radiogenic argon, because the time interval involved is negligible in geological terms<sup>5</sup>. The pegmatites formed a late stage part of the Paraíba activity so the age of the Paraíba orogeny may be taken to be lower to middle Cambrian, and not early Pre-Cambrian as had previously been thought<sup>6</sup>, and the age of the Barbacena orogeny to be around  $1.150 \times 10^6$  yr, from the evidence of the Volta Grande pegmatite.

We thank Dr J. A. Miller and Dr A. Gilbert Smith for their help and advice.

## PHYSICS

### Measurement of Ionization Potentials from Contact Charge Transfer Spectra

THE use of charge transfer spectra for the evaluation of ionization potentials is well known. Thus Foster has found an empirical relationship between the ionization potentials of condensed ring aromatic hydrocarbons and the frequencies of maximum absorption of their charge transfer complexes with chloranil in carbon tetrachloride<sup>1</sup>. Foster's formula is limited to the condensed ring aromatic hydrocarbons because the binding of electron donors to acceptors in charge transfer complexes is not caused entirely by charge transfer; intermolecular forces vary between different classes of molecules and influence complex formation. In general, the relationship between the ionization potential and the frequency of maximum absorption of the charge transfer complex is given by

$$h\nu = I_p - E_A - \frac{e^2}{r} - \Delta$$

where  $I_p$  is the ionization potential of the electron donor,  $E_A$  is the electron affinity of the electron acceptor,  $\frac{e^2}{r}$  is the coulombic interaction between the two and  $\Delta$  represents all the other intermolecular forces<sup>2</sup>. There exists a type of charge transfer between molecules which does not produce a bound complex and is termed contact charge transfer<sup>3</sup>. The electron donors and acceptors are randomly disposed in solution but when they come into contact with each other momentary charge transfer takes place which gives rise to an absorption spectrum. One electron acceptor which takes part in contact charge transfer is oxygen<sup>4</sup>. Measurements made of its equilibrium constant with electron donors yield a value of zero<sup>4,5</sup>. Furthermore, the absorption band caused by this type of charge transfer increases to higher frequency without having a maximum absorption peak, the type of behaviour that can be predicted for transitions occurring between energy levels which show no minima, that is two non-bonding levels. Because there is no binding in contact "complexes" it would appear that a very general relationship can be set up between the ionization potentials of electron donors and the onset of absorption of the charge transfer band arising with oxygen.

The absorption spectra of a wide range of electron donors with oxygen dissolved in chloroform under 120 atmospheres has been measured in an apparatus essentially the same as that described by Evans<sup>4</sup>. The absorption spectra of the charge transfer complexes with chloranil in carbon tetrachloride have also been measured. The results are shown plotted as the frequency of maximum absorp-

\* Ref. 6. † Measured in water. ‡ Obtained from the chloranil spectrum.

tion of the charge transfer band in electron volts against the frequency of onset of oxygen absorption.

It can be seen that the molecules fall into several distinct groups. The condensed ring aromatic hydrocarbons fall on a straight line as do the aliphatic amines and the amides, these lines being at  $45^\circ$  to the axes. A fairly satisfactory fit of the aminoquinoline derivative, chloroquine, can also be obtained to a line of heterocyclic nitrogen compounds. Furthermore, the straight lines are parallel showing that there is a constant difference of interaction between the different groups of molecules. Foster's rule for the condensed ring aromatic hydrocarbons is

$$I_p = 5.12 + 1.13 h\nu_{CT} \text{ (eV)}$$

Using this rule to relate the ionization potential to onset of oxygen absorption gives the equation

$$I_p = 5.24 + 1.13 h\nu_0 \text{ (eV)}$$

Fig. 1.

Values of ionization potentials derived from the oxygen absorption are given in Table 1 and are contrasted with values obtained from photodissociation studies<sup>6</sup>. The values agree reasonably well and, what is more important, show the same trends. The results are also in satisfactory agreement with polarographic measurements of electron donation<sup>7</sup>. One advantage of this method is that it is more readily applicable than the usual methods of measuring ionization potentials, which depend on obtaining molecules in their vapour phase. Many large organic or biological chemicals have too low a vapour pressure for such measurements to be made. Measurements of charge transfer complexes with oxygen have certain advantages over those with chloranil. The latter reacts with a number of the amines used in this study to produce strongly absorbing products. Under the conditions in the experiments reported here there is no irreversible reaction, as shown by the reversibility of the spectral changes on removal of oxygen. The fact that a wide range of electron donating compounds can readily produce charge transfer complexes, however, may have interesting implications in biology.

### Scanning Ion Microscopy and Ion Beam Micro-machining

FOR some years it has been possible to focus beams of electrons into fine probes with diameters in the range 10  $\mu\text{m}$ –100  $\text{\AA}$ . These have been used for electron beam machining, electron probe analysis and scanning electron

microscopy. Progress in focusing ion beams has been more limited. Notably, Gabbay *et al.*<sup>1</sup> have used a beam of lithium ions from a coated tungsten hair-pin filament and have reported a resolution of the order of  $3\text{ }\mu\text{m}$  in a scanning ion microscope. The only work in which very fine beams of rare gas ions have been used appears to be that of Saporin *et al.*<sup>2</sup>, who have reported a final beam diameter of  $10\text{--}15\text{ }\mu\text{m}$  at  $30\text{ kV}$ . von Ardenne<sup>3</sup> has described two systems, one using a canal-ray source and the other a capillary source in which ions were focused to about  $5\text{ }\mu\text{m}$ , but in this case the final lens used was of very short focal length and the focus was not readily accessible.

Much larger beams of  $100\text{ }\mu\text{m}$  and above have been used in ion-bombardment sources in mass spectrometers<sup>4-8</sup> and by Kanaya *et al.*<sup>9</sup> for ion beam machining.

One of us has discussed the possibility of obtaining a useful current of rare gas ions in a beam of the order of  $1\text{ }\mu\text{m}$  in diameter<sup>10</sup> and assessed the feasibility of using an ion probe for making localized measurements of isotopic abundance with a spatial resolution comparable with that obtained in electron probe X-ray microanalysis. An ion probe mass spectrometer with a high spatial resolution is being developed in this laboratory and it has been possible to determine the performance of the ion probe-forming system by using it as a scanning ion microscope and for ion beam machining.

At present, the instrument uses a duoplasmatron source<sup>11</sup> similar in design to that described by Moak *et al.*<sup>12</sup> followed by two electrostatic condenser lenses to form a probe of argon ions. The source itself operates at a pressure of approximately  $10^{-2}$  torr and differential pumping across apertures is used to maintain a good vacuum in the specimen chamber. The scanning technique used to form images of the surface is similar to that used in scanning electron microscopy, deflexion of the beam being achieved by electrostatic plates placed after the final lens. This lens is so designed that it may be operated with a clear working distance of  $4\text{ cm}$ . Ions impinging on the specimen cause secondary electrons to be produced by Auger and resonance neutralization and by kinetic emission<sup>13</sup>. These electrons are collected by an accelerating scintillation detector of the type devised by Everhart and Thornley<sup>14</sup>. Contrast in the image is thus

Fig. 1. Scanning ion micrograph showing 1,500 t.p.i. silver mesh ( $20\text{ keV}$  argon ions).

due to variation in the yield of secondary electrons from point to point and may arise from variations in specimen inclination, chemical composition, crystal orientation or electrical potential and from the presence of electrical or magnetic fields. In the examples shown, the contrast is topographic, that is, it arises from varying inclination of the specimen surface. The image of a 1,500 t.p.i. silver mesh inclined at  $45^\circ$  to the incident ion beam is illustrated in Fig. 1. The bars of the mesh are approximately  $4\text{ }\mu\text{m}$  wide and examination of the surface features indicates a resolution of the order of  $0.5\text{ }\mu\text{m}$ .

Fig. 2. Scanning ion micrograph showing results of ion beam machining on a 1,500 t.p.i. silver mesh ( $20\text{ keV}$  argon ions).

The sputtering rate for silver bombarded by  $20\text{ keV}$  argon ions can be estimated approximately from the data of Almén and Bruce<sup>15</sup>. For an angle of incidence of  $45^\circ$ , the rate of removal of silver is of the order of  $0.017\text{ }\mu\text{m/sec}$  for a current density of  $1\text{ amp/cm}^2$ . The current density at which the scanning pictures were taken was  $13\text{ amp/cm}^2$ . The same beam was used to cut through two of the grid bars (thickness  $2.5\text{ }\mu\text{m}$ ) shown in Fig. 1. At A (Fig. 2) a slightly defocused beam has been used, while at B the diameter of the beam used was close to the minimum size obtained. The time taken to cut through the whole width of the grid bar in the latter case was about  $2\text{ min}$ , in reasonable agreement with the calculated time on the basis of the rate of removal given here.

It has been found possible to operate the system with a  $1\text{ }\mu\text{m}$  probe and a current density of up to approximately  $0.6\text{ amp/cm}^2$ , and thus fairly rapid machining is possible. The rate of cutting even at this value is considerably slower than that obtainable by electron beam techniques but the use of ions has the advantage that, for reasonable current densities, the process is non-thermal. Furthermore, experience with the present instrument suggests that the beam diameter may be reduced below  $0.5\text{ }\mu\text{m}$ , making even finer machining possible. It should be noted that for fine beams and deep cuts redeposition of sputtered material on the sides of the hole or groove will influence the rate of sputtering. Initially, the outer parts of the bombarded area will be eroded slowly compared with the centre as a result of the Gaussian distribution of current in the beam. As the hole develops, however, the rate of erosion in the peripheral areas should increase because of the increase in angle of incidence. The final hole may therefore be expected to have steep sides rather than a simple Gaussian profile.

## THE SOLID STATE

### Tensile Strength of Granular Materials

THE contribution by Carr<sup>1</sup> on the tensile strength of granular materials raises two issues of fundamental importance: first, the validity of the equation for tensile strength proposed by Smalley and Smalley<sup>2</sup>

$$\sigma \simeq 4.6 \frac{Bt}{D^3} \quad (1)$$

where  $B$  is the interparticle force per contact,  $D$  is the diameter of the particles and  $t$  is the thickness of the fracture zone; and secondly, the manner in which  $B$  varies with the degree of saturation. Equation 1 was derived on the assumption that fracture occurs on a plane normal to the tensile direction and that the particles intersected by this plane come apart without themselves contributing to the strength. For granular materials, where the bonding is provided by the capillary action of water, rupture of the particles is never possible.

The approach may be used, however, to determine the number of particles involved in the rupture and it may be assumed that these will be equally divided between the two broken surfaces. Hence the number of particles  $P$  in each face is given by

$$P = \frac{3\rho A_a}{\pi D^2} \quad (2)$$

where  $\rho$  is the density of packing and  $A_a$  is the gross area of the section. The mean exposed surface of the particles will be hemispherical, so that if  $k$  is the number of bonds per particle the total number of broken bonds,  $N$ , is  $0.5Pk$ .

The size of each bond site is governed by the size of the particles and, for particles of equal diameter, a site occupies a small circle of diameter  $0.5D$ . If the bonds are uniformly distributed over the surface, equal areas will contain equal numbers of bonds, the tensile component of each bond being  $B \cos \theta$ , where  $\theta$  is the angle between the bond and tensile directions. Hence the mean tensile component  $B_m$  is given by

$$B_m = 0.5B \quad (3)$$

The tensile strength of the entire mass is then

$$\begin{aligned} \sigma A_a &= (0.5Pk)(0.5B) \\ &= \frac{3\rho A_a k B}{4\pi D^2} \end{aligned}$$

or

$$\sigma = \frac{3\rho k B}{4\pi D^2} \quad (4)$$

and accepting the value of  $\rho = 0.6$  given by Scott<sup>3</sup> and  $k = 8.0$  obtained from the experimental data of Bernal and Mason<sup>4</sup>

$$\sigma = \frac{3.6B}{\pi D^2} \quad (5)$$

To obtain the strength of an actual test specimen, this value must be modified by consideration of an appropriate failure criterion. The Mohr-Coulomb criterion (see Skempton and Bishop<sup>5</sup>) gives the tensile strength at failure as

$$\sigma_f = \frac{3.6B}{\pi D^2} \cdot \frac{(1 - \sin \varphi)}{(1 + \sin \varphi)} \quad (6)$$

where  $\varphi$  is the internal angle of friction of the material.

Equation 6 agrees with the corresponding equations by Rumpf<sup>6</sup> and Smalley and Smalley<sup>2</sup> in that the tensile strength is found to be directly proportional to  $B$ . The Haines-Fisher<sup>7</sup> equation for  $B$  is

$$B = \pi DT / (1 + \tan \frac{1}{2} \theta) \quad (7)$$

where  $2\theta$  is the angle subtended at the centre of the particle by the lens of water and  $T$  is the surface tension. Hence  $B$ , and consequently the tensile strength, will increase with reducing moisture content. This conclusion, however, is contrary to the experimental results quoted by Carr, and elsewhere in the literature.

The common factor in the derivation of each of the equations for tensile strength is the concept of a model consisting of particles connected by a finite number of bonds. An examination of moisture characteristics relating the energy of retention of water in the liquid phase to the water content for granular materials with uniform grains indicates that, following the initial air entry, the bulk of the water is removed at a constant energy level and only in the final stages is there an increase in the energy per unit volume. For the present example, energy of retention may be equated to capillary pressure. At any stage, the material can be considered as consisting of two parts: that in which air entry has occurred; and that in which it has not. As each succeeding section drains, it passes from the saturated to the drained state at constant energy level and the effective stress on the sample decreases by a factor of approximately 0.3 while the previously drained sections undergo only a minor stress change. Following this reasoning, Aitchison<sup>8</sup> proposed the following equation

$$\sigma = p.S + 0.3 \int_0^S p dS \quad (8)$$

where  $p$  is the energy of retention and  $S$  is the degree of saturation. For a constant energy of retention, equation 8 reduces to

$$\sigma = p(0.7S + 0.3) \quad (9)$$

from which

$$\sigma_f = p(0.7S + 0.3) \frac{(1 - \sin \varphi)}{(1 + \sin \varphi)} \quad (10)$$

Tensile strengths obtained by Carr<sup>1</sup>, Pearce and Donald<sup>9</sup> and Fowler and Radford<sup>10</sup> are shown in Fig. 1. Pearce and Donald quote their results in terms of  $T/r$  and it has been assumed that they used a value of 50 dynes/cm for  $T$ . Fowler and Radford quote moisture content and net degree of saturation and their results have been converted by the use of compaction data obtained by me.

Fig. 1. Tensile strength of granular materials.  $\times$ , Fine coal<sup>1</sup>;  $\blacktriangle$ , 204 $\mu$  (ref. 10);  $\circ$ , 170 $\mu$  (ref. 9). The line is the evaluation of equation 10, assuming the internal angle of friction,  $\phi$ , is 30°.

None of the writers quotes moisture characteristics for their materials but because all particles are of the order of 200 $\mu$ , an air entry value of 30 g/cm<sup>2</sup> will be assumed. If a  $\phi$  value of 30° is also assumed, equation 10 may be evaluated. The evaluation is shown in Fig. 1 and it looks a reasonable approximation. The fit is usually considerably better when the correct energy of retention and  $\phi$  is known for each point. In the final stages of desiccation there should be a transition from equation 8 to equation 5 and it is observed that only the more carefully prepared samples of Pearce and Donald show any indication of this. I have obtained similar results with very fine grained materials by allowing them to come to equilibrium at constant humidity for periods of up to twelve months.

The ultimate value of  $B = \pi DT$ , however, is not approached for two reasons. One is that this value infers an infinite tensile stress in the water but the tensile strength of water is thought to be about 200 kg/cm<sup>2</sup> and is probably much less in practical situations. The other reason is that the changing nature of the material from ductile to brittle must also be taken into account. Carr's notion of "dry joints", for example, is a simple statement of the Griffith<sup>11</sup> crack theory for brittle materials which would predict a maximum tensile strength of

$$\sigma_f = 0.5\sigma \tan \phi \quad (11)$$

and this should replace the Mohr-Coulomb theory in the later stages.

The basic difficulty encountered in this field of research stems from the desire to obtain a simple single failure

theory for a material which adopts a wide range of physical characteristics with variations in moisture content.

## CHEMISTRY

### Surface Photopolymerization of Vinyl and Diene Monomers

WHITE has shown that gaseous 1,3-butadiene in contact with metallic substrates polymerizes under the influence of ultra-violet light<sup>1</sup>. In contrast to surface photopolymerization induced by electron beams<sup>2-5</sup> or in glow discharges<sup>6-10</sup>, little has been published about the process induced by photons. I have obtained results on deposition from butadiene and on the extension of this method for surface polymerization from the gas to other monomers, with concomitant formation of novel materials in thin film form.

A 700 W medium pressure Hanovia mercury arc provides a convenient source for surface photopolymerization of such vinyl monomers as acrylonitrile, methyl methacrylate, and styrene, and diene monomers such as 1,3-butadiene and 2,4-hexadiene. Effective ultra-violet radiation over the range 2000–3500 Å is transmitted to the substrate area by means of a quartz window. The system is pre-evacuated to a pressure of about 10<sup>-6</sup> torr, chiefly to remove water vapour, and the gaseous monomer is then maintained at a pressure of about 4 torr during the irradiation.

As indicated by White<sup>1</sup>, the growth rates for photopolymerization exhibit a negative dependence on substrate temperature, with activation energies in the neighbourhood of -8 kcal/mole. Similarities in the structure of the films deposited from the various monomers to those of the analogous polymers produced by conventional techniques demonstrate that the low energies of the photon irradiation permit retention of the characteristics of the individual monomer. Multiple infra-red absorption data, however (Fig. 1), show that the films from C<sub>4</sub>H<sub>6</sub> are not simply polybutadiene. They indicate the presence of CH<sub>3</sub> groups (~1,375 cm<sup>-1</sup>), CH<sub>2</sub> groups (~1,450 cm<sup>-1</sup>), and aliphatic CH groups (~2,950 cm<sup>-1</sup>), as well as some small amounts of carbon-carbon triple bonds (~3,300, 2,110 and 697 cm<sup>-1</sup>). Furthermore, at least thirteen gas phase products have been identified from the 1,3-butadiene photopolymerization. Absorption at ~966 cm<sup>-1</sup> suggests that the thermodynamically favoured *trans*-1,4 form of addition may be preferred under these reaction conditions. The films which we deposited from butadiene are unique in that when thicker than about 5000 Å, they are unstable in the presence of air or moisture at high temperatures. They assume a "cracked" appearance, show birefringent behaviour, and may spontaneously peel from metallic substrates.

Hexachlorobutadiene represents an unusual type of "monomer" which is subject to polymerization by this tech-

Fig. 1. Infra-red spectrum of film from  $C_6H_6$ , five reflexions from a film about 20,000 Å thick on evaporated aluminium.

Fig. 2. Log of growth rate of films from  $C_2Cl_4$  on evaporated aluminium against  $1/T$ .

nique. The steric hindrance effect of the halogen atoms makes this molecule quite inert in conventional reaction systems. It does not react with chlorine at temperatures as high as 500° C (refs. 11 and 12), cannot serve as the diene component in the Diels-Alder reaction<sup>13,14</sup> and does not react with sulphuryl chloride in the presence of benzoyl peroxide<sup>15</sup>. It does not undergo any significant free radical copolymerization with styrene<sup>16</sup>. Fig. 2 illustrates growth rate behaviour from the vapour at about 100μ, that is vapour in equilibrium with the liquid monomer source maintained at 18° C in a shaded part of the system.

The solid circle represents growth on an uncooled substrate surface which becomes heated to about 177° C by the mercury arc. The Arrhenius plot indicates a negative activation energy of about -8.5 kcal/mole. The photopolymerized films are essentially transparent in the infra-red. The perchlorinated deposit shows a carbon to chlorine atomic ratio of approximately 2:1, while chlorine has been identified as the principal gas phase product. The surface reaction therefore involves considerable chlorine elimination and is obviously quite complex. The films exhibit high thermal stability. For example, unlike the films from hydrocarbon monomers, no significant carbon monoxide infra-red absorption can be detected on exposure to steam at 100° C. An exothermic reaction, however, does occur in nitrogen at temperatures above 300° C and the films lose weight.

It is also possible to polymerize tetrafluoroethylene by this technique. Fig. 3 illustrates the structure of the continuous transparent films deposited from the gas at a pressure of about 1 torr onto substrates maintained at a temperature of about 30° C. The growth rate is about 30 Å/min under these conditions. Although elemental analysis shows an atomic ratio similar to that in polytetrafluoroethylene, the presence of some  $CF_3$  groups is indicated by absorption at  $\sim 980\text{ cm}^{-1}$ . The absence of crystal-crystal transitions on differential scanning calorimetry, and loss of weight in air beginning at about 220° C, suggest the presence of a considerable amount of low molecular weight material in the as-polymerized films.

The extremely thin films that may be deposited by the ultra-violet surface photopolymerization process are uniquely suited to electron microscopic studies of morphology. Although it has long been evident from the pioneering work of Storks<sup>17</sup> and Till<sup>18</sup> that electron diffraction offers a powerful tool for investigation of crystallinity in polymers, the need for specimens sufficiently thin to permit electron transmission has tended to limit the technique to specimens crystallized from solution or melt. After removal from metallic or other substrates by dissolving the latter in concentrated acids, the inert films produced by photopolymerization may be examined directly in transmission without need for sectioning, carbon support or replication.

Fig. 3. Infra-red spectrum of film from  $C_2F_4$ , five reflexions from each of two parallel evaporated aluminium slides with polymer films about 2000 Å thick.

Fig. 4. Electron diffraction pattern from film deposited from  $C_4Cl_6$  obtained with a Siemens 'EMI' electron microscope.

Selected area electron diffraction studies on the as-polymerized films showed evidence for single-crystal structures as illustrated for the films from  $C_4Cl_6$  in Fig. 4. This structure is not representative of the films as a whole and occurs in only a minute fraction of the surface area. Attempts at shadowing indicated the structures to be within the films rather than on either surface. Repeat distances of about 18 and 11 Å for rotations of  $60^\circ$  about the hexagonal—or pseudohexagonal—pattern are remarkably constant for deposition from a wide range of monomers. Similar values for deposition on various metallic and non-metallic substrates indicates that the regularity does not simply correspond to an epitaxial overgrowth on the substrate such as that which appears to occur during gamma irradiation of trioxane in the presence of large single crystals of monomer<sup>19,20</sup>. Perhaps localized crystallization of largely carbonaceous by-products common to the monomers results in minute regions of extreme order. The thickness of the films (a few hundred Å) could permit the long period of the lamellae<sup>21</sup> to lie parallel to the beam of electrons as they pass through the polymeric films within the microscope.

I thank R. A. Mazzarella and W. R. Burgess for assistance with depositions and R. N. Chrenko and W. J. Barnes for the infra-red and electron microscope measurements.

## Tin Oxide— $Sn_3O_4$

DURING the 170 years since the preparations of stannous and stannic oxides were first reported<sup>1,2</sup>, many authors have claimed to have shown the existence of oxides of tin the compositions of which were intermediate between the two. Included in the most recent of these are the papers by Spandau and Kohlmeier<sup>3</sup> and Spinedi and Gauzzi<sup>4</sup>, who report  $Sn_3O_4$ , and Decroly and Ghodsi<sup>5</sup>, who contend that  $Sn_5O_6$  is formed. No data concerning the crystal structure of the intermediate oxides have so far been given.

In order to verify that an intermediate oxide existed a series of isothermal experiments were carried out in which dry stannous oxide was heated in an atmosphere of nitrogen free from oxygen for times varying from 15 min to 16 h at temperatures between  $700^\circ$  K and  $1,050^\circ$  K. The resultant disproportionation products were analysed non-destructively by the use of electron diffraction, X-ray diffraction and Mössbauer spectroscopy. Electron micrographs were prepared to enable phase identifications to be made.

Besides metallic tin and stannic oxide, a new phase was evident in those samples which were heated for short times or at low temperatures. This material was always in the form of thin single crystal platelets measuring about  $1000 \text{ Å}$  square and  $50 \text{ Å}$  thick. The extremely small size of the crystals made it impossible to separate the platelets from the associated  $\beta$ -tin globules and the very fine stannic oxide crystallites, and so all analyses had to be carried out on material containing all three species. X-ray and electron diffraction analyses showed that the crystal habit of the platelet was triclinic with

$$\begin{aligned} a &= 4.86 \pm 0.16 \text{ Å} \\ b &= 5.88 \pm 0.14 \text{ Å} \\ c &= 8.20 \pm 0.17 \text{ Å} \\ \alpha &= 93^\circ 00' \pm 0.17' \\ \beta &= 93^\circ 21' \pm 21' \\ \gamma &= 91^\circ 00' \pm 24' \end{aligned}$$

The large maximum probable errors are the direct result of using powder data rather than single crystal data for the calculation of the unit cell dimensions.

The principal X-ray diffraction lines for the new phase are

<i>hkl</i>	<i>d</i>	<i>I/I<sub>0</sub></i>
001	8.17	15
011	4.84	30
002	4.08	5
101	3.301	25
012	2.916	33
021	2.827	15
112	2.793	30
112	2.778	5
003	2.721	100
021	2.645	50
112		

In all, 110 reflexion lines which are attributable to the new phase were found.

From considerations of the theoretical density of a crystal with the dimensions as given, and of the transformation mechanism necessary to convert stannous oxide to the intermediate material, the most probable composition of the new phase is  $Sn_3O_4$ . Mössbauer spectra obtained using a  $^{119m}\text{Sn}$  source were not inconsistent with a formula  $Sn_2^{II}Sn^{IV}O_4$  for the phase.

The metastable material decomposes on further heating into  $\beta$ -tin and stannic oxide. The kinetics of the decomposition are first order with respect to the intermediate oxide. The two reactions occurring during the disproportionation of stannous oxide are:

Differential thermal analysis measurements show that the disproportionation is indeed a two step process, both reactions being irreversible. This latter point is to be expected because stannous oxide, as a condensed phase, is itself thermodynamically unstable with respect to  $\beta$ -tin and stannic oxide<sup>6</sup>.

### Crystal Structure of Meisenheimer Complex

CHEMICAL and spectroscopic evidence exist for the equivalence of the attached substituent groups of Meisenheimer complexes<sup>1</sup>, but the detailed structure of these complexes has not as yet been elucidated. We report here the structure of the 1,1-dimethoxy-2,4,6-trinitrobenzene ion. The crystal analysed was

and was obtained by recrystallization from acetonitrile. The space group and the unit cell dimensions are triclinic,  $PI$  with  $a = 9.36$ ,  $b = 10.84$ ,  $c = 7.40 \pm 0.02$  Å,  $\alpha = 87^\circ 40'$ ,  $\beta = 106^\circ 43'$ ,  $\gamma = 102^\circ 45' \pm 20'$ ,  $Z = 2$ ,  $d$  calc = 1.65, and  $d$  obs = 1.64.

The structure was determined by a three-dimensional Patterson synthesis, and the refinement was carried out by the least squares method with isotropic temperature factors. The  $R$ -value at the present stage is 0.169 for 1,897 reflexions. The bond distances are shown in Fig. 1.

Fig. 1. Structure of Meisenheimer complex.

and the average standard deviation is 0.018 Å. It is remarkable that the two methoxy groups are attached to the benzene ring with the same bond distances. The atoms C-7, O-1, O-2 and C-8 lie almost in a plane, and this plane makes an angle of  $87^\circ 50'$  with the benzene ring plane. Although the angle C-2, C-1, C-6 is  $109^\circ 48'$ , which is nearly equal to the tetrahedral angle, the benzene ring is still nearly planar, the largest deviation at C-2 being 0.03 Å.

Of the three nitro groups, that at the *para*-position and another at the C-1 *ortho*-position are twisted approximately  $6^\circ$ , while the third one at the C-6 *ortho*-position is twisted as much as  $11^\circ 42'$ . The difference in bond distances between C-1, C-6 and C-1, C-2 may be correlated with this difference of twisting. Except for this asymmetry all structures are nearly symmetrical; in particular, the two methoxyl groups are confirmed to be equivalent. All calculations were carried out at the Computation Centre of the University of Tokyo; the least square programme was supplied by the UNICS system.

### BIOPHYSICS

#### Effect of Gases on the Electrical Conductivity of $\beta$ -Carotene

We have studied the semiconductive and photoconductive properties of single crystals of  $\beta$ -carotene<sup>1</sup>. During these and other studies, changes in the electrical conductivity in the presence of oxygen have been observed<sup>1,2</sup>. The effect of gases on the conductivity of other organic crystals<sup>3-8</sup> has indicated that these changes are caused by donor-acceptor interactions between the gas and the crystal. Studies of this type have been largely carried out with anthracene, which is generally regarded as an electron donor, and chloranil, an electron acceptor.  $\beta$ -Carotene, it has been said, should be both a good electron donor and also a good electron acceptor<sup>9</sup>. These properties of  $\beta$ -carotene are of interest in relation to Platt's theory of the role of  $\beta$ -carotene in the primary photosynthetic process<sup>10</sup>, and may be relevant to the mechanism of olfaction where it has been proposed that interactions between gas molecules and carotenoids may be involved<sup>11-13</sup>. Here we present the results of an initial qualitative survey of the effect of various gases and vapours on the conductivity of single crystals of all *trans*  $\beta$ -carotene.

The methods of obtaining crystals of all *trans*  $\beta$ -carotene and of making conductivity measurements have been previously described<sup>1</sup>. The studies reported here were confined to surface conductivity measurements in the *ab* plane of the crystal. 'Aquadag' was used throughout as the electrode material. The dark and photoconductivity of the crystals were measured *in vacuo* after a small amount of gas or vapour had been admitted to the dewar.

The dark conductivity of  $\beta$ -carotene *in vacuo* is rather low at room temperature ( $\rho \sim 10^{17}$ /ohm cm). To be sure of observing both decreases and increases in conductivity most measurements were made at  $70^\circ\text{C}$ . Some measure-

Table 1. QUALITATIVE EFFECT OF GASES ON THE SURFACE CONDUCTIVITY OF ALL *trans*  $\beta$ -CAROTENE

Gas or vapour	Change in dark conductivity	Change in photoconductivity
O <sub>2</sub>	+	+
SO <sub>2</sub>	+	+
HCl	+	0
C <sub>2</sub> H <sub>5</sub> OH	+	0
(CH <sub>3</sub> ) <sub>2</sub> CO	+	0
CH <sub>2</sub> Cl <sub>2</sub>	+	0
CHCl <sub>3</sub>	+	0
(C <sub>2</sub> H <sub>5</sub> ) <sub>3</sub> N	+	-
C <sub>6</sub> H <sub>6</sub>	0	0
H <sub>2</sub> O	0	0
CH <sub>3</sub> OH	0	0
N <sub>2</sub>	0	0
A	0	0
CO <sub>2</sub>	0	0
NH <sub>3</sub>	(-)	(-)
I <sub>2</sub>	0	(-)

+, Increase in current; -, decrease in current; 0, no observable change in conductivity. All changes were reversible, except for those in brackets.

ments were also made at lower temperatures but these tended to be complicated by changes which were induced by the ambient gases in the insulation resistance of the apparatus. The photocurrents were measured using white light from a tungsten lamp.

The qualitative effects of the various gases and vapours on the dark and photoconductivity of all *trans*  $\beta$ -carotene are listed in Table 1. With the exception of CH<sub>2</sub>Cl<sub>2</sub> and CHCl<sub>3</sub>, these effects were all observed at 70° C. With these gases it was difficult to establish a change in conductivity at this temperature, but at 40° C a clear increase in dark conductivity was observed.

The effects of hydrogen chloride and sulphur dioxide were largely reversed when the dewar was evacuated, but the rate of return of the current to its vacuum level was very slow. For example, in a typical experiment the dark current rose from  $2.0 \times 10^{-12}$  amps *in vacuo* to  $6.5 \times 10^{-11}$  amps in the presence of SO<sub>2</sub>. When the SO<sub>2</sub> was removed and the dewar continuously pumped, the current slowly fell to a value of  $5.8 \times 10^{-12}$  amps during a period of 17 h. (The difference between this and the original current may have been caused by the difficulty of completely outgassing the crystal. The possibility of a small permanent change in the  $\beta$ -carotene crystal cannot, however, be ruled out.) A rather similar result was obtained with hydrogen chloride.

The changes in conductivity range in magnitude from a factor of two to a factor of fifty. In general, the effect of the gases on the photoconductivity was less marked than the effect on the dark conductivity. A definite change in the photoconductivity could be detected for only three gases.

The irreversible changes observed with iodine and ammonia probably indicate that a permanent chemical change has occurred at the surface of the crystal. If we consider only reversible changes the results can be summarized as follows. (a) Both electron donor and acceptor gases increase the surface dark conductivity. (b) The photoconductivity is less affected by ambient gases than is the dark conductivity. (c) There is some suggestion that the photoconductivity is increased by electron acceptors and decreased by electron donors. More evidence is required to establish this conclusion. (d) Inert gases and gases which have only very weak charge transfer properties have no observable effect on the conductivity.

These results are not sufficient for unique determination of the nature of the interactions between the gas molecule and the crystal. It is, however, reasonable to suppose that the increases in dark conductivity which we observe with both donor and acceptor gases are caused by the injection of electrons and holes respectively. This implies that both electrons and holes can contribute effectively to the conductivity of  $\beta$ -carotene. This is confirmed by previous photoconductivity studies with strongly absorbed light which indicate that the hole current is only two to three times greater than the electron current<sup>1</sup>.

The relatively weak effect of ambient gases on the photoconductivity is almost certainly a consequence of

the photoconductivity spectrum of  $\beta$ -carotene. It has been found that charge carriers are most efficiently produced by weakly absorbed light in the bulk of the crystal<sup>1,14</sup>. Thus gases adsorbed on the surface of the crystal might be expected to have little effect on this process.

The increases in photoconductivity observed with oxygen and sulphur dioxide and the decrease observed with tri-ethylamine are in agreement with changes produced by these gases in the photoconductivity of anthracene. In this material it is not clear whether the gases affect the lifetime of the hole or the production of the charge carrier<sup>15</sup>. In  $\beta$ -carotene the effect of tri-ethylamine, which is to decrease the photocurrent while increasing the dark current, is most simply explained by supposing that it is the charge carrier production which is affected in the photoconductivity measurements.

We thank Mr D. E. Graham for technical assistance.

## Liquid Crystalline Behaviour in Mixtures of Cholesterol with Steroid Hormones

THE liquid crystalline behaviour of mixtures of cholesterol with glycerol and cetyl alcohol has been reported by Młodziejowski<sup>1</sup>, cholesterol molecules being "plasticized" by the molecules of glycerol or cetyl alcohol. Although cholesterol itself is not mesomorphic, all cholesterol esters have characteristic mesophases. It is possible that the hydrogen bonding in pure cholesterol is responsible for the high melting point because the presence of glycerol or cetyl alcohol molecules may provide alternative sites to which hydroxyl groups of the cholesterol molecules hydrogen can bond without imposing a high melting temperature on the crystal lattice but having a sufficiently strong intermolecular attraction to make an anisotropic melt possible.

The molecular interaction of steroid hormones with cholesterol and lecithin<sup>2</sup> spread as surface monolayers on a Langmuir trough suggests that a physiochemical basis may exist which determines the uptake of steroid hormones into cell membranes. Potential binding sites would then be dependent on the phospholipid and cholesterol composition of the membranes<sup>3,4</sup>. The steroid hormones are a group of lipids differing only slightly in chemical structure but having fairly precise target organs and effects. The selective uptake of steroids into cells may be determined by their solubility within the lipid membrane because this solubility is greatly affected by small structural changes.

The present investigation has been of the phase equilibrium behaviour of mixtures of cholesterol with some of the steroid hormones. We have preferred to use a technique of thaw melting to a procedure of thermal analysis because mesomorphic transitions were common and were most easily observed directly or with the use of crossed polarizers. Gray has outlined the limitation of this method of identification<sup>5</sup>. The steroids, cholesterol, progesterone, androstenedione, testosterone, dehydroisoandrosterone, cortisol, oestrone and oestradiol, were used as supplied. They all had melting points in agreement with published ratios.

The solid mixtures were prepared by melting small weighed amounts on watch glasses and allowing them to solidify. Cortisol and oestrone decomposed during this treatment and no phase diagram could be obtained, but in all other cases no variability in the results was experienced.

The mixtures of the steroid hormones with cholesterol all showed mesomorphic transitions that were noted as softening points as the temperature was increased (smectic mesophase) or regions of less viscous liquid (cholesteric mesophase), which again became stiff until finally flowing to form an isotropic liquid state. It was not possible to detect the mesophase transitions on cooling.

Dehydroisoandrosterone with cholesterol (Fig. 1) showed the most interesting liquid crystalline behaviour. Mixtures in the range of composition with 30–40 per cent cholesterol all softened at very low temperatures and individual crystals ran together. Above this temperature the mixture stiffened, forming what appeared to be a stepped smectic liquid crystalline phase which softened and hardened through three other liquid crystalline phases before melting to a clear, free running isotropic liquid. Examination of all these mixtures under cross polaroids was only advantageous in determining the final liquid phase but did not help to distinguish the liquid crystalline phases.

The phase equilibrium curves obtained for mixtures of cholesterol with progesterone, testosterone and androstenedione were all similar. The mixtures showed slight

Fig. 1. Phase equilibrium curve for cholesterol-dehydroisoandrosterone mixtures, above *GHI* (smectic mesophase), above *BC* (cholesteric mesophase), above *AE* (cholesteric mesophase), above *AFD* (isotropic liquid).

Fig. 2. Phase equilibrium curve for cholesterol-oestradiol mixtures, below *BGH* (smectic mesophase), above *BGH* (cholesteric mesophase), above *AEDIF* (cholesteric mesophase), above *ADF* (isotropic liquid).

softening at the edges at temperatures in the range 40°–80° C as the temperature was increased. A temperature was then reached at which free liquid separated at the edges (cholesteric mesophase), but this later hardened and finally rapid melting was noted. Complete isotropic liquid appeared a few degrees higher.

The mixtures of cholesterol with oestradiol (Fig. 2) behaved differently in that they showed the formation of a complex at a 3:2 molecular ratio although on each side of this complex the transitions noted were similar to those observed with the other steroids.

These results show that the steroid hormones in cholesterol mixtures cause anisotropic melts which give rise to eutectic points as indicated (*E*). In all but one case the point *E* corresponds to a 1:1 mixture. Although the eutectic point does not usually signify complex formation, it is here taken to correspond to the most favourable packing ratio, giving rise to maximum reduction in the melting point. Such a favourable molecular packing ratio is found in other systems<sup>2,3</sup>.

Dehydroisoandrosterone shows the most interesting polymorphism and the eutectic occurs at a 2:1 molecular ratio. The most noticeable difference is that dehydroisoandrosterone has a double bond in the 5:6 position, whereas progesterone, testosterone and androstenedione all have a double bond in the 4:5 position.

Oestradiol is also different in showing the formation of a definite complex with cholesterol under the conditions of preparation corresponding to a 3:2 molecular ratio. Such differences, however, are to be expected and can be compared with the effect of double bond position or variation of  $\alpha$  and  $\beta$  stereo groups in the mesomorphic behaviour of steroid esters<sup>6</sup>.

Such properties may relate to the biological activity and localization of steroid hormones in cell membranes.

## BIOCHEMISTRY

Glucose-phosphorylating Enzyme with High  $K_m$  in Human Brain

THE recent discovery of an insulin-inducible glucose-phosphorylating enzyme with high  $K_m$  ("glucokinase", ATP-D-glucose 6-phosphotransferase, *E.C.* 2.7.1.2.) in the liver<sup>1,2</sup> and epididymal fat pad<sup>3</sup> of small laboratory animals has added to the current interest in the mechanisms which control glucose metabolism in mammalian tissues. No evidence from kinetic studies<sup>4-6</sup> or electrophoresis<sup>5,7</sup>, however, has yet been obtained for the occurrence of an analogous enzyme with high  $K_m$  in the brains of rats, guinea-pigs or sheep and the view has grown that this type of activity is absent from the brain.

In the tissues where it has been found, activities of glucokinase have been shown to be affected by fasting, post-natal development, insulin and alloxan diabetes<sup>1-3,8</sup>. The report<sup>9</sup> that the human brain is sensitive to insulin, although the response is slower than that of peripheral tissues, led me to investigate the possibility that glucokinase of high  $K_m$  may be present in human brain although it is apparently absent from the brains of the lower mammals (rat, guinea-pig and sheep) which have been studied.

Because the glucokinase in the liver has been reported to be relatively labile<sup>10</sup> and because of the extremely rapid post-mortem changes in the brain of concentrations of relevant chemicals such as glucose<sup>11</sup>, glycogen<sup>12</sup> and ATP<sup>13</sup>, samples should be used immediately after excision, if possible, in this type of investigation. Post-mortem samples are usually difficult to obtain within a few hours after death, when marked autolysis is likely to have occurred. On the other hand, the use of biopsy specimens often involves uncertainty as to the normality of the sample.

The samples which I used were biopsy specimens of cerebral cortex obtained during neurosurgery (Table 1).

The samples were frozen in the operating theatre directly after excision except for sample 4, which was used immediately. All subsequent procedures were performed at 0°-2° C. Adhering dural membranes and blood vessels were removed and the cortex was rapidly snipped off with scissors, weighed and homogenized in 0.32 molar sucrose (adjusted to pH 7.4 with potassium hydroxide) in a 'Teflon'-pestle homogenizer to a final suspension of 10 ml./g fresh tissue. In one case (sample 3), the cortex was divided into two parts and homogenized in two different media: (1) 0.32 molar sucrose, pH 7.4; and (2) 0.25 molar sucrose, 0.05 molar glucose, 0.005 molar cysteine, 0.01 molar KCl, 0.005 molar MgCl<sub>2</sub> and 0.005 molar ATP, pH 7.4. Subcellular fractions were prepared by differential centrifugation; in the work reported here the extracts used were the soluble supernatant fractions obtained by centrifugation at 150,000*g* av. for 60 min.

Glucose-phosphorylating activities were estimated in a final volume of 3 ml. containing 150 mmolar glycylglycine, pH 8.0; 10 mmolar MgCl<sub>2</sub>; 5 mmolar ATP; 0.25 mmolar NADP<sup>+</sup>, 0.2 IU glucose-6-phosphate dehydrogenase and glucose as indicated. The assay solutions were prepared in 1 cm light-path cuvettes in a Unicam 'SP 800' recording spectrophotometer equipped with a constant temperature cell housing maintained at 37° C. After equilibration for 5 min the reactions were started by the addition of 50-100  $\mu$ l. of extract and continued for 15 min at 340 m $\mu$ .

Table 1. SOURCES OF HUMAN CEREBRAL CORTX SAMPLES

No.	Sex	Reason for neurosurgery	Site	Sample Pathology
1	F	Sclerosis of hippocampus	Temporal lobe	Normal tissue
2	F	Hypophysectomy for breast cancer	R. frontal lobe	Normal tissue
3	M	Suspected glioma	Temporal lobe	Normal tissue*
4	M	Suspected glioma	Temporal lobe	Normal tissue

\* The possibility of infiltration of this sample by tumour tissue could not be excluded.

Fig. 1. Reciprocal plot of glucose-phosphorylating activity against glucose concentration (0.1-400 mmolar). ●, Sample 1; ○, sample 4.

using reference cells which contained all the constituents except glucose and ATP.

Reciprocal plots of activity ( $\Delta E/\text{min}$ ) against concentration of glucose were made for concentrations of glucose from 0.1 to 400 mmolar. The extracts from all specimens yielded similar results—two are shown in Fig. 1 (samples 1 and 4).

There was a sharp point of inflexion in the plots at about 2 mmolar glucose. The point of inflexion was not as sharp nor was the increase in activity at higher concentrations of glucose as large as those observed by Walker<sup>1</sup> in liver preparations and no inhibition of the low  $K_m$  hexokinase activity at high concentrations of glucose<sup>1</sup> was detected.

Extrapolation of the plots between 0.1 and 2 mmolar glucose gave  $K_m$  values of 0.05 mmolar (Table 2). The plots (Fig. 1) for concentrations of glucose between 100 mmolar and 400 mmolar have been re-drawn<sup>1</sup> on an expanded scale (Fig. 2). Extrapolation of the plots gave  $K_m$  values of 21 mmolar (Table 2). The presence in the homogenization medium of glucose, ATP, potassium chloride and thiol groups, which might be expected to exert a stabilizing influence on a potentially labile enzyme of this type<sup>10</sup>, did not seem to have much effect (Table 2, samples 3a and b). Because the point of inflexion in the reciprocal plots (Fig. 1) occurred at about 2 mmolar glucose, this concentration was used to calculate the quantitative difference between the activities of the low and high  $K_m$  system. The activity of the low  $K_m$  system was calculated from the rate of formation of NADPH at 2 mmolar and the high  $K_m$  from the difference between the rates at 200 mmolar and 2 mmolar (Table 3).

Fig. 2. Reciprocal plot of glucose-phosphorylating activity against glucose concentration at high glucose concentration. The points are the first five from Fig. 1 presented on an expanded abscissa scale. ●, Sample 1; ○, sample 4.

Table 2. *K<sub>m</sub>* VALUES OF GLUCOSE-PHOSPHORYLATING SYSTEMS FROM HUMAN CEREBRAL CORTEX

Sample	Low <i>K<sub>m</sub></i> (mmolar)	High <i>K<sub>m</sub></i> (mmolar)
1	0.053	22
2	0.043	21
3a	0.053	24
3b	—*	22
4	0.057	18

The *K<sub>m</sub>* values were obtained from extrapolations of the reciprocal plots of Figs. 1 and 2.

\* It was impossible to measure this value because the glucose in the brain extract (resulting from the 50 mmolar glucose present in the sucrose used for homogenization) resulted in minimal glucose concentrations in the assay medium of 0.8–1.7 mmoles/l.

Table 3. CALCULATED LOW *K<sub>m</sub>* AND HIGH *K<sub>m</sub>* GLUCOSE-PHOSPHORYLATING ACTIVITIES IN EXTRACTS OF HUMAN CEREBRAL CORTEX

Sample No.	Activity (μmoles NADPH/min/g original tissue)	Low <i>K<sub>m</sub></i> enzyme	High <i>K<sub>m</sub></i> enzyme	Total
1	3.7	1.8	5.5	5.5
2	2.25	1.6	3.85	3.85
3a	1.6	1.2	2.8	2.8
4	3.75	1.7	5.45	5.45
Guinea-pig cerebral cortex*	5.5	0.0	5.5	5.5
Rat liver†	0.6	1.46	2.06	2.06

The low *K<sub>m</sub>* activity was calculated from the rate of formation of NADPH at 2 mmolar glucose and the high *K<sub>m</sub>* activity from the difference in rates between 2 mmolar and 200 mmolar glucose.

\* Non-particulate high-speed supernatant fraction from guinea-pig cerebral cortex\*.

† Salas, Vinuela and Sols\* used in rat liver extracts the rate at 0.5 mmolar glucose and the difference in rates between 0.5 mmolar and 100 mmolar glucose for the activities of hexokinase and glucokinase, respectively.

The results show clear and consistent evidence for the presence of an enzyme of high *K<sub>m</sub>* in human cerebral cortex which may be a "glucokinase" analogous to the insulin-inducible enzyme found in other tissues. Until some correlation between activity and physiological conditions similar to those found<sup>1-3,8,10</sup> for the enzymes in the liver and fat pad has been shown, however, it would be premature to assume that it is a truly analogous enzyme, even though the human brain has been shown to be sensitive to insulin<sup>9</sup>. Because no evidence has been obtained for the presence of an enzyme of high *K<sub>m</sub>* in guinea-pig, rat or sheep brain<sup>4-7</sup>, it provides an interesting and unusual difference between the brains of man and the lower mammalian orders.

The *K<sub>m</sub>* is higher (21 mmolar) than has been reported for rat liver or guinea-pig liver glucokinases<sup>1</sup> and the ratio of high *K<sub>m</sub>* to low *K<sub>m</sub>* activity in the human cerebral cortex is lower than the ratios reported for the liver systems<sup>1,2</sup>. Glucokinase activities in the liver have been shown to fall as a result of fasting<sup>8</sup>, however, and it must be borne in mind that pre-operative care always involves fasting for some hours so the actual levels of the high *K<sub>m</sub>* activity in the human brain may well be higher than those reported here.

The relative consistency of the results for the high *K<sub>m</sub>* activity (Table 3) suggests that the enzyme is stable in the frozen intact tissue, because the result from sample No. 4 (which was fresh when used) was not very different from those obtained for the other samples (which had been stored frozen for varying times before homogenization). On the other hand, the high *K<sub>m</sub>* activity decreased rapidly but inconsistently after dispersion when stored either at 3° C or at -20° C. The assays were routinely performed on the same day as the tissues were homogenized. Inclusion of glucose, ATP, KCl and cysteine in the sucrose used to prepare the extracts had little stabilizing effect—the high *K<sub>m</sub>* activity had disappeared within a few days at -20° C in samples 1–3. The activity lasted longer in sample 4 which was not frozen before use—it remained relatively stable for 5 days at -20° C and then slowly disappeared. The possibility of separating the high *K<sub>m</sub>* activity from the low *K<sub>m</sub>* enzyme will depend on the development of the right conditions for stabilizing the activity.

The presence of two kinetically distinct glucose-phosphorylating enzymes in the human cerebral cortex is of

relevance to the peculiar requirement of the brain for glucose and in view of the suggestion<sup>14</sup> that enzymes of this type provide one of the control points of glycolysis in the brain. It is difficult at this stage to assess the significance of the presence of a glucose-phosphorylating enzyme of such a high *K<sub>m</sub>* without the ability to vary the physiological conditions; however, similar studies (my unpublished work) on monkey brain indicate that it also contains the high *K<sub>m</sub>* activity and so should provide the opportunity for studying its significance in terms of control mechanisms.

This work was supported by a grant from the Bethlem Royal Hospital and the Maudsley Hospital Research Fund. I thank Professor H. McIlwain for his support and interest, Mr M. Falconer and Mr P. Shurr of the Guy's Maudsley Neurosurgical Unit for providing the specimens, Professor P. Daniel and Dr L. W. Duchon of the Neuropathology Department for advice in the pathology of the specimens and Mr A. Holliman for technical assistance.

### Growth Hormone and Carbohydrate Metabolism *in vitro*

ONE *in vivo* effect of growth hormone secreted by the anterior pituitary gland is to oppose the action of insulin in promoting the utilization of glucose in muscle (see ref. 1 for earlier references), an effect which is almost certainly of physiological significance<sup>2,3</sup>. Nevertheless, no satisfactorily reproducible effect of growth hormone *in vitro* on carbohydrate metabolism has been described. Rather surprisingly Park *et al.*<sup>4</sup> observed that the addition of growth hormone *in vitro* to diaphragm from the hypophysectomized rat stimulates the uptake of glucose, that is, growth hormone exerts an insulin-like action in this system. This observation has been confirmed<sup>5</sup> but is not reproducible with diaphragm from intact rats (see ref. 6 for further references). The amount of growth hormone added to diaphragm *in vitro* in these experiments was 1 μg/ml. or more.

Using methods similar to those of Manchester and Young<sup>5</sup> we have observed that with diaphragm from hypophysectomized rats the addition *in vitro* of a much smaller amount of growth hormone than has previously been used under such conditions significantly diminishes the glucose uptake (Table 1). The curious biphasic dose-response curve observed in respect of the addition of very small amounts of growth hormone *in vitro* is illustrated in Fig. 1. With the addition of about 4 μg/ml. the previously observed insulin-like action of growth hormone on the uptake of glucose is seen, but with 0.8 per cent of this concentration (32 μg/ml.) a substantial depression of

Table 1. EFFECT OF OX GROWTH HORMONE (76 GH1) ADDED *in vitro* ON GLUCOSE UPTAKE AND ON THE INCORPORATION OF GLYCINE U-<sup>14</sup>C INTO PROTEIN OF THE ISOLATED DIAPHRAGM FROM MALE HYPOPHYSECTOMIZED RATS KILLED 11-13 DAYS AFTER HYPOPHYSECTOMY

Concentration of ox growth hormone in medium (mμg/ml.)	Glucose uptake (% of basal value)	P Control versus experimental	Increase in glycine U- <sup>14</sup> C incorporation (% of basal value)	P Control versus experimental
6.4	-17.8 ± 3.3* (12)	< 0.001	+19.7 ± 4.9 (12)	< 0.01
32.0	-25.0 ± 2.2 (11)	< 0.001	+23.0 ± 2.6 (11)	< 0.001
160.0	-6.8 ± 4.5 (11)	> 0.1	+19.7 ± 4.7 (11)	< 0.01
800.0	+8.8 ± 2.1 (8)	< 0.01	+27.3 ± 4.2 (8)	< 0.001
4,000.0	+33.0 ± 5.0 (6)	< 0.001	+32.0 ± 7.0 (6)	< 0.001

\* Standard error of the mean value. The figures in parentheses indicate the number of rats used to provide the mean value cited.

glucose uptake occurs (Fig. 1), which is abolished by the addition to the medium of 0.6 mU of insulin/ml., a dose which is approximately 32 mμg/ml. of insulin.

The addition to diaphragm from the hypophysectomized rat of similar amounts of growth hormone *in vitro* stimulates the incorporation of radioactive glycine into protein, the dose-response curve being very flat (Fig. 2) and showing no tendency to be biphasic with very small amounts of growth hormone.

When ox growth hormone is added *in vitro* to diaphragm from normal rats, a qualitatively similar effect on the uptake of glucose is seen (Fig. 3), but the variability of the observations is much greater than with diaphragm from hypophysectomized rats and the dose-response curve is very flat indeed. Similar observations have been made with human growth hormone *in vitro*.

These results show that when a very small amount of growth hormone is added to rat diaphragm *in vitro* under suitable conditions, an action can be observed which is

Fig. 1. Effect of addition of ox growth hormone (76 GH1) *in vitro* on the uptake of glucose by isolated diaphragm from hypophysectomized rats killed 11-13 days after hypophysectomy. The heights of the histograms indicate mean values and the lengths of the vertical lines at the top of the histograms indicate twice the standard error of the mean value. The figures in parentheses in the histograms indicate the number of rats used to provide the mean value.

### Glucose Metabolism in Fat Cells stimulated by Insulin and dependent on Sodium

SPECIFIC transport of organic and inorganic substances through biological membranes has been well established<sup>1</sup>. Transport of organic substances, such as amino-acids and sugars, may be active and is, as a rule, linked to the

transport of cations<sup>2</sup>, most frequently those of sodium and potassium<sup>3</sup>. Other transport mechanisms may agree rather with the definition of facilitated diffusion which seems to be independent of cations<sup>4</sup>. It is usually thought that in insulin tissues such as muscle and adipose tissue which respond to insulin, this hormone somehow favours the facilitated diffusion of glucose and of certain other sugars<sup>5,6</sup>. Insulin also facilitates, however, the entry of some substrates which pass through by active transport<sup>7</sup>, and, furthermore, it has been shown to increase the resting electrical potential of muscle<sup>8</sup> and of adipose tissue<sup>9</sup>, while stimulating decreasing retention of potassium and sodium ions respectively in these tissues<sup>10,11</sup>. While Hagen<sup>12</sup> has reported that insulin has less effect on glucose metabolism by adipose tissue in the absence of sodium or potassium ions, Rodbell<sup>13</sup> has observed normal responsiveness to insulin of isolated fat cells in the absence of sodium ions. These conflicting views have encouraged us to investigate the effects of changing the concentration of cations in the medium glucose transport and metabolism by isolated fat cells, both in the presence and absence of insulin. A marked sodium dependency of insulin-stimulated glucose metabolism in fat cells on sodium has been found.

Well-fed male mice 6-7 weeks old were used. The fat cells were isolated<sup>14</sup> from epididymal fat pads and incubated in Krebs-Ringer bicarbonate buffer containing 3.5 per cent albumin and 2.5 mmolar glucose-U<sup>14</sup>C (40  $\mu$ C/mmol). After 2 h the incorporation of the carbon of glucose into carbon dioxide<sup>15</sup> and total lipids<sup>16</sup> was measured. These metabolic indices were used as an indirect estimate of glucose uptake, because their sum has been shown to represent 80-90 per cent of total glucose metabolism in these conditions<sup>17,18</sup>. Results are expressed as  $\mu$ atoms of glucose carbon incorporated into carbon dioxide or total lipids, of lipid weight/2 h of incubation. Insulin concentration, when used, was 1 mU/ml. When sodium ions were omitted from the incubation medium, it was replaced by an equivalent amount of another cation.

Table 1. EFFECT OF DEPLETION OF SODIUM IONS ON GLUCOSE-U<sup>14</sup>C METABOLISM BY FAT CELLS

Medium Na <sup>+</sup> (mequiv./l.)	Control	Insulin (1 mU/ml.)	Insulin effect
Glucose- <sup>14</sup> C to CO <sub>2</sub>			
144	2.78 $\pm$ 0.01	12.2 $\pm$ 0.22	9.42
0	3.50 $\pm$ 0.11	7.22 $\pm$ 0.49	3.12
144	1.58 $\pm$ 0.02	11.8 $\pm$ 0.10	10.2
0	3.68 $\pm$ 0.11	8.10 $\pm$ 0.22	4.42
144	2.31 $\pm$ 0.10	9.78 $\pm$ 0.22	7.47
0	3.49 $\pm$ 0.30	5.28 $\pm$ 0.28	1.79
Glucose- <sup>14</sup> C to total lipids			
144	4.55 $\pm$ 0.05	21.9 $\pm$ 0.14	17.4
0	5.15 $\pm$ 0.32	10.4 $\pm$ 0.08	5.25
144	6.47 $\pm$ 0.22	36.8 $\pm$ 0.18	30.3
0	14.2 $\pm$ 0.10	26.6 $\pm$ 0.41	12.4
144	3.73 $\pm$ 0.19	17.4 $\pm$ 0.12	13.7
0	6.16 $\pm$ 0.20	12.1 $\pm$ 0.65	5.94

Results are expressed as  $\mu$ atoms C metabolized/g of lipid/2 h; mean of 6  $\pm$  SEM. Glucose, 2.5 mmolar; sodium was replaced by potassium ions.

Complete replacement of sodium ions by potassium ions in the absence of insulin (Table 1) reproducibly resulted in a moderate stimulation of glucose incorporation into both carbon dioxide and total lipids, showing that this treatment did not result in a non-specific inhibition of metabolic activity of the cells. In the presence of insulin, however, the opposite was the case: overall metabolic activity was decreased by one-third, while the insulin effect (total activity in the presence of insulin minus total activity in the absence of insulin) was decreased by two-thirds. These results might be the consequence of either the depletion of sodium ions or the high concentration of potassium ions, so that replacement of sodium ions by other ions was also investigated, while the concentration of potassium ions was kept constant (6 mequiv./l.). Replacement of sodium ions by *tris* or by choline (Table 2) caused a similar or greater depressive effect of the depletion of sodium ions on glucose metabolism in the presence of insulin. Furthermore, progressive depletion of sodium ions in the presence of insulin (Table 3) resulted in progressive depression of the metabolic indices measured.

Table 2. EFFECT OF REPLACEMENT OF SODIUM IONS BY OTHER CATIONS ON THE METABOLISM OF GLUCOSE-U<sup>14</sup>C BY INSULIN-STIMULATED FAT CELLS

Medium Na <sup>+</sup> (mequiv./l.)	Replaced by	<sup>14</sup> C to CO <sub>2</sub>	<sup>14</sup> C to total lipids
144	—	16.9 $\pm$ 0.33	25.8 $\pm$ 0.46
0	Tris <sup>+</sup>	5.82 $\pm$ 0.10	8.49 $\pm$ 0.20
144	—	16.1 $\pm$ 0.12	26.9 $\pm$ 0.46
0	Choline <sup>+</sup>	6.92 $\pm$ 0.14	10.2 $\pm$ 0.25
144	—	12.2 $\pm$ 0.22	21.9 $\pm$ 0.14
0	K <sup>+</sup>	7.22 $\pm$ 0.49	10.4 $\pm$ 0.68

Results are expressed as in Table 1; insulin 1 mU/ml.

These results agree with those of Hagen<sup>12</sup>, which demonstrated that glucose uptake in adipose tissue induced by insulin was decreased in the absence of sodium ions. This influence of sodium depletion could be the result of action exerted at almost any point of glucose uptake or metabolism on the end-products measured. As has already been pointed out, however (Table 1), depletion

Table 3. EFFECT OF PROGRESSIVE DEPLETION OF SODIUM IONS IN THE PRESENCE OF INSULIN

Medium Na <sup>+</sup> (mequiv./l.)	<sup>14</sup> C to CO <sub>2</sub>	<sup>14</sup> C to total lipids
144	16.9 $\pm$ 0.33	25.8 $\pm$ 0.46
72	10.5 $\pm$ 0.27	15.6 $\pm$ 1.35
50	7.08 $\pm$ 0.26	10.2 $\pm$ 0.17
25	6.55 $\pm$ 0.22	9.07 $\pm$ 0.28
10	8.14 $\pm$ 0.36	8.32 $\pm$ 0.35
0	5.82 $\pm$ 0.10	8.49 $\pm$ 0.20

Results are expressed as in Table 1; insulin 1 mU/ml.

of sodium ions did not apparently decrease glucose metabolism in the absence of insulin. Furthermore, glucose enters adipose tissue cells by a carrier-mediated process of facilitated diffusion<sup>6,19</sup>, which is usually the rate-limiting step of glucose metabolism in this tissue. Insulin enhances the rate of diffusion by this process. The simplest hypothesis to explain dependency of glucose metabolism on sodium in the presence but not in the absence of insulin would be that of insulin activation of an otherwise inactive carrier<sup>20</sup> which would require sodium ions before accepting glucose molecules for transport across the membrane, with subsequent liberation of sodium ions and glucose at the internal surface.

# Inhibition of True Cholinesterase in TOCP Poisoning with Potentiation by 'Tween 80'

SINCE the work of Earl and Thompson<sup>1,2</sup> on hens, and the brief note by Mendel and Rudney<sup>3</sup> on rats, it has often been accepted<sup>4,5</sup> that in tri-ortho cresyl phosphate (TOCP) intoxication, pseudocholinesterase is markedly inhibited but that there is little or no decrease in true cholinesterase. A decrease in red blood cell cholinesterase has, however, been reported in rabbits<sup>6</sup> and a slight fall in man<sup>7</sup> after treatment with TOCP by mouth, and Taylor<sup>8</sup> has commented on parasympathomimetic effects in cats injected with this compound. I have investigated changes in cholinesterase in baboons after oral doses of TOCP. Monkeys have been found to be very resistant to TOCP by mouth<sup>9,10</sup> and it has been suggested the monkeys do not absorb it from the gut. In addition to pure TOCP therefore a 10 per cent emulsion in 10 per cent 'Tween 80' has also been tried in the present work at the suggestion of Dr J. D. Taylor of the Department of Pharmacology, University of Alberta. He has found this emulsion more active than the pure substance (personal communication from J. D. Taylor). The results to be described show that after administration of either preparation to the baboon, pseudocholinesterase is very readily inhibited, but that marked inhibition of true cholinesterase also occurs. In the reports of TOCP poisoning in man after accidental ingestion, diarrhoea and abdominal pain have often been noted and have sometimes been severe<sup>11</sup>. These effects would be expected to accompany inhibition of true cholinesterase.

The effects of pure TOCP were not uniform. Baboons *F* and *J* developed moderate diarrhoea within 24 h and this persisted for 48–72 h. Baboon *F* had slight limb weakness during this time, but neither it nor baboon *J* showed fasciculation and neither was seriously ill. Baboon *L*, which also showed the most marked changes in cholinesterase, was much more severely affected and was moribund when killed 7 days after poisoning. Diarrhoea was very severe, body weight falling by 20 per cent in the first 24 h and the skeletal muscles showed widespread coarse fasciculation and weakness. Fasciculation ceased after 4 days, but weakness persisted until death.

The effects of emulsified TOCP showed less variation, and were greater than those of the pure compound, despite the fact that the dose was reduced by 60 per cent (see Table 1). Baboons *H* and *K* both developed diarrhoea, severe muscle weakness and fasciculation. Baboon *G* suffered only slight anorexia after the first dose, given at the same time as atropine, but after the second was affected as severely as *H* and *K*. 'Tween 80' alone had no effect on concentrations of cholinesterase even in a large dose. The potentiating effect of 'Tween 80' could be caused by increased intestinal absorption of TOCP. Future toxicity testing of other aryl phosphates used in industry should perhaps take account of this.

The effect of atropine on baboon *I* was unexpected. Atropine was given at the same time as the emulsified TOCP, and 24 h later the animal was well except for a little anorexia. Table 1 shows that true cholinesterase fell much less sharply than in baboons *H* and *K*, and so the well-being of the animal was probably not caused only

Table 1. VALUES FOR CHOLINESTERASE IN RED BLOOD CELLS, MUSCLE, AND PLASMA BEFORE AND AFTER TOCP AND 'TWEEN 80'

Baboon	Weight (kg)	Dose TOCP (ml/kg)	'Tween 80' (ml/kg)	Atropine (mg intra-muscular)	Red blood cell cholinesterase + MCh ( $\mu$ l. CO <sub>2</sub> /ml./min)			Muscle cholinesterase + MCh ( $\mu$ l. CO <sub>2</sub> /g/min)			Plasma cholinesterase + BuCh ( $\mu$ l. CO <sub>2</sub> /ml./min)

\* Normal values not available for this animal. Figures are the mean and standard deviation of the other normal values in the table.

† Given 5 weeks after the dose of 'Tween 80' above.

‡ Given 24 h after the first dose.

The weights of the animals, the dose given to each and the corresponding concentrations of cholinesterase are shown in Table 1. All were sexually mature females, of species *P. papio* and *P. anubis*. The preparations of TOCP provided by Drs H. F. Bondy and K. R. Payne of Coalite and Chemical Products, Ltd., were at least 99 per cent pure; they were made from ortho-cresol, in which phenol, about 0.5 per cent, was the only identifiable impurity. They were given by gastric tube under light phenacyclidine anaesthesia. Cholinesterase was estimated with a conventional Warburg manometric apparatus<sup>2</sup> with butyrylcholine perchlorate (BuCh) and acetyl  $\beta$ -methylcholine chloride (MCh) (Koch-Light) as substrates for pseudo and true cholinesterase respectively. Red blood cells were separated from plasma by centrifuging heparinized blood, washed three times in 0.88 per cent sodium chloride, and finally lysed by adding distilled water up to the volume of the original blood sample. For estimation of muscle cholinesterase, *M. palmaris longus* was washed free of obvious blood in 0.88 per cent sodium chloride, lightly blotted, dissected free of connective tissue, and minced. The mince was then homogenized in 0.25 molar sodium bicarbonate to give 1 g of mince/4 ml. of homogenate. Blood and muscle were taken before and 21–27 h after poisoning, each animal thus providing its own control.

by blocking the parasympathomimetic effects of acetylcholine excess. Possibly atropine, given in large dose at the same time as the poison, delays or reduces intestinal absorption.

I thank Professor R. W. Gilliatt for his encouragement and advice, Dr G. R. Webster for guidance in the cholinesterase estimations and Dr J. D. Taylor for suggesting the use of 'Tween 80'. I also thank the MRC for a personal grant.

## Uptake of Steroid Hormones into Artificial Phospholipid/Cholesterol Membranes

THE effect of steroid hormones on the movement of ions<sup>1,2</sup> and glucose<sup>3</sup> across artificial lipid membranes has been studied, but their activity in such membranes has not been correlated with their concentration within the membranes. The problem of uptake of steroid hormones into lipid membranes has been the subject of speculation and experiment<sup>4-7</sup>, and the work reported here has been carried out in order to examine this problem further.

The lipids used in this study were egg lecithin, which was chromatographically purified, after which it runs as a single peak in chromatographic systems with a characteristic  $R_F$  value; cholesterol, which was recrystallized from redistilled 'AnalaR' grade petroleum ether (40°–60° C); and chromatographically pure dicetylphosphate. Each of the tritiated steroids (in amounts of 5  $\mu$ c.) was added to 1 l. of water.

Table 1. DISTRIBUTION COEFFICIENTS OF FIVE STEROID HORMONES BETWEEN A LIPID MYELIN SUSPENSION AND WATER

Membrane 1 (90 per cent lecithin, 10 per cent dicetylphosphate)		
Aldosterone	1.125 $\pm$ 0.017	(30)
Cortisol	1.322 $\pm$ 0.041	(78)
Deoxycorticosterone	1.840 $\pm$ 0.060	(200)
Oestrone	3.191 $\pm$ 0.062	(520)
Progesterone	4.080 $\pm$ 0.030	(730)
Membrane 2 (80 per cent lecithin, 10 per cent dicetylphosphate, 10 per cent cholesterol)		
Aldosterone	1.113 $\pm$ 0.024	(28)
Cortisol	1.302 $\pm$ 0.020	(75)
Deoxycorticosterone	1.502 $\pm$ 0.080	(119)
Oestrone	2.978 $\pm$ 0.014	(491)
Progesterone	3.861 $\pm$ 0.068	(710)
Membrane 3 (70 per cent lecithin, 10 per cent dicetylphosphate, 20 per cent cholesterol)		
Aldosterone	1.111 $\pm$ 0.033	(29)
Cortisol	1.277 $\pm$ 0.041	(72)
Deoxycorticosterone	1.390 $\pm$ 0.070	(93)
Oestrone	2.823 $\pm$ 0.049	(477)
Progesterone	3.650 $\pm$ 0.040	(694)
Membrane 4 (60 per cent lecithin, 10 per cent dicetylphosphate, 30 per cent cholesterol)		
Aldosterone	1.133 $\pm$ 0.021	(37)
Cortisol	1.270 $\pm$ 0.014	(75)
Deoxycorticosterone	1.406 $\pm$ 0.080	(96)
Oestrone	2.577 $\pm$ 0.055	(460)
Progesterone	3.320 $\pm$ 0.040	(647)

Values in parentheses are the corresponding lipid : water distribution coefficients.

The membranes were prepared by adding appropriate amounts of the lipids in chloroform solution to each of four 100 ml. flasks, giving a total of 250  $\mu$ moles lipid in the proportions indicated in Table 1. These were evaporated to dryness, 50 ml. of water was added to each and they were shaken for 1 h. The flasks were allowed to stand overnight and reshaken before use. Spherical myelins formed, which were examined by electron microscopy after staining with a 2 per cent solution of phosphotungstic acid and found to provide very good bimolecular structures as described in previous work<sup>3</sup>.

After the final shaking, aliquots of 2 ml. were removed and dialysed against 40 ml. volumes of each steroid solution. These were left to stand overnight—which was found to be a suitable time for equilibrium to be established—after which 1 ml. of the inside and outside solutions were transferred to separate counting vials. The water was removed by standing on a hot plate, and scintillation fluid was then added to each vial and the tubes counted.

It was found that the presence of the small amount of lipid had no quenching effect on a tritium standard, and therefore the distribution coefficients for the steroids between the spherulite suspension and water could be directly obtained by taking the ratio of the counts for the corresponding inside and outside solutions (Table 1). The experiment was repeated and for each steroid with each membrane twelve values were obtained which have been used to determine a mean and a standard deviation.

The values of these distribution coefficients have been converted to a corresponding lipid : water distribution coefficient, which may be useful in the estimation of the distribution of the steroid hormones in the lipoidal environment of binding tissue<sup>8</sup>.

The effect of steroid concentration was investigated and the distribution coefficient found to remain constant up to concentrations of steroid approaching their limiting water solubilities, which have been determined as: cortisol ( $6.2 \times 10^{-4}$  moles/l.); deoxycorticosterone ( $1.6 \times 10^{-4}$  moles/l.); aldosterone ( $1.2 \times 10^{-4}$  moles/l.); oestrone ( $7.6 \times 10^{-5}$  moles/l.); and progesterone ( $2.7 \times 10^{-5}$  moles/l.).

A comparison of these water solubilities with the distribution coefficients suggests that the distribution coefficient reflects a decreased solubility in water rather than an increased solubility in the lipid membranes. The presence of cholesterol in the membrane lowers the membrane solubility of the steroid hormone, the distribution coefficient varying linearly with the cholesterol content. Such observations may be relevant to problems of uptake and localization of the steroid hormones in cells.

## Production of Ethanol and Succinate by *Moniliformis dubius* (Acanthocephala)

LAURIE<sup>1,2</sup> found that formate, acetate and lactate were the chief excretory products from the carbohydrate metabolism of *Moniliformis dubius*, and we have found lactate and succinate to be the most important excretory products of *Polymorphus minutus*, an acanthocephalan parasite of domestic ducks<sup>3</sup>. Succinate has been reported as an intermediary metabolite of the carbohydrate metabolism of *M. dubius*<sup>4,5</sup>, and so we decided to analyse for excretory products, in particular succinate, the medium in which specimens of *M. dubius* had been incubated.

*M. dubius* was maintained in the laboratory using cockroaches, *Periplaneta americana*, as the intermediate hosts, and Wistar rats as the final hosts. Adult worms 42–57 days old were recovered from the rats and washed thoroughly in Tyrode saline, before being incubated in Tyrode saline containing <sup>14</sup>C-glucose at pH 7.5 and 37° C under commercial nitrogen. Incubation was terminated after a certain time, and the worms were removed and weighed and the medium was analysed for volatile components, non-volatile acids and residual glucose. The results given below apply to an incubation, lasting 2.5 h, of 515 mg wet weight of worms with 5 mg of glucose in 3.4 ml. of saline.

Examination of a sample of the medium using a gas chromatograph with a flame detector revealed that the main excretory product of *M. dubius* was neither formate nor acetate but another very volatile non-acidic substance, and analysis showed that most of the excreted radioactivity was associated with this metabolite. The substance was found to have the same retention time as

ethanol on the gas chromatograph, and support for its identity was obtained on incubation with yeast alcohol dehydrogenase. In conditions of low oxygen tension the production of ethanol was of the order of 200  $\mu\text{g}/100$  mg wet weight of worms/h for the 2.5 h of incubation. A similar quantity of ethanol was produced when another batch of worms was incubated aerobically. By comparison, the amount of acetate excreted by the worms was about 54  $\mu\text{g}/100$  mg wet weight of worms/h, but the radioactivity associated with the acetate was only one-sixtieth of that of the ethanol. This result indicates that most of the acetate had not been produced directly from the absorbed radioactive glucose. No formate could be detected.

Non-volatile organic acids were detected and identified as described before<sup>3</sup>. Radioactivity was associated only with lactic and succinic acids, the former being thirty-three times as active as the latter. It was found that 85 per cent of the original glucose had been metabolized by the worms during the incubation and, of this, about 30 per cent was excreted as ethanol, 2.3 per cent as lactate and succinate, and 0.5 per cent as acetate. Similar results were obtained on two other occasions.

The identification of ethanol among the excretory products of *M. dubius* provides the first record known to us of the formation of this substance by an acanthocephalan worm. It is possible that much of the unidentified, volatile radioactive component found<sup>5</sup> in homogenates of *M. dubius* incubated with <sup>14</sup>C-glucose was also ethanol. Ethanol is known to be a minor excretory product of the cestodes *Echinococcus granulosus*<sup>6</sup> and *Taenia taeniaeformis*<sup>7</sup>. It is clear from our investigation that ethanol is the principal excretory product of *M. dubius*, but succinate has also been found to be excreted.

We are grateful to Dr S. J. Edmonds of the Department of Zoology, University of Adelaide, for sending eggs of the parasite.

### Vinca Alkaloids and the Synthesis of RNA in Mouse Brain

THE dimeric indole alkaloids, vinblastine and vincristine, were isolated during the investigations<sup>1,2</sup> of the reported hypoglycaemic activity<sup>3</sup> of *Vinca rosea* Linn. Although the occurrence of hypoglycaemia could not be substantiated, the alkaloids were found to be potent oncolytic agents in some experimental systems<sup>4</sup>. Clinically, vinblastine has been useful in the treatment of lymphoma, including Hodgkin's disease, carcinomata of the breast and bronchus and certain non-malignant conditions such as Letterer-Siwe disease<sup>5</sup>. Vincristine has been used with varying degrees of success in acute lymphocytic and myelogenous leukaemia, carcinoma of the cervix, malignant lymphomata, neuroblastoma, Wilms' tumour and rhabdomyosarcoma<sup>6</sup>, as well as in certain intracranial gliomata<sup>7</sup>. Both alkaloids may suppress the immune response<sup>8</sup>. Whereas leukopenia has been the limiting manifestation of toxicity in the use of vinblastine<sup>9</sup>, this has

not usually been the case with vincristine, which produces various neuropathies<sup>10</sup> with a picture of polyneuritis running an acute or sub-acute course<sup>11</sup>. In mice, vincristine produces degeneration of the dorsal root cells and of the myelin sheath of the sciatic and median nerves, and inhibits the proliferation of the Schwann cells<sup>12</sup>. The present study was undertaken in an attempt to find a biochemical basis for the neurotoxicity.

White mice (Swiss CD-1) were used; they were given 'Purina' laboratory chow and water freely. Vinca alkaloids, as the sulphate salts, dissolved in isotonic saline, were administered by daily intraperitoneal injections in doses of between 0.1 and 0.5 mg/kg. Single injections of vincristine, or of 4  $\mu\text{c}$ . of either uridine-<sup>3</sup>H (specific activity 2.6 c/mmole) or valine-1-<sup>14</sup>C (specific activity 22 mc./mmole), dissolved in 0.05 ml. of isotonic saline, were given intracranially. These injections were divided so that half was administered to lightly anaesthetized mice into each side of the brain at a point midway between the eye and ear. Intraperitoneal injection of vincristine in doses of 0.3 and 0.5 mg/kg produced signs of neurological toxicity by the seventh day, starting as insensitivity to pain in the tail and digits, and progressing through diminished activity to hind limb palsy. Single intracranial injections of vincristine in doses as small as 0.03 mg/kg produced neurotoxicity by the fourth day after treatment. The manifestations included loss of sensitivity to pain, periods of uncoordinated and frenzied motion, hind limb palsy and almost total paralysis of the limbs leading to death; these signs were not seen in controls treated with saline. Vinblastine given by daily intraperitoneal injections did not produce obvious signs of neurological toxicity, except perhaps a marked depression in activity, but only 10 per cent of the mice survived more than 14 days of treatment.

The synthesis of brain RNA was studied by injecting tritiated uridine intracranially after different periods of intraperitoneal treatment, and killing the animals 30 min later. Brains were removed, washed with cold isotonic saline and homogenized with cold 0.5 molar perchloric acid. After washing five or six times with the same acid, the residues were extracted with absolute ethanol: ether (3:1) to remove lipid, and RNA was hydrolysed by heating with 0.2 normal sodium hydroxide for 30 min at 90°. The solutions were acidified with 0.5 molar perchloric acid, cooled in ice, centrifuged, and the supernatant fractions which contained ribonucleotides derived from RNA were assayed for ultra-violet absorbance at 260 m $\mu$  with a Zeiss 'PMQII' spectrophotometer, and for radioactivity, using a Packard 'Tri-Carb' scintillation spectrometer. Fig. 1 shows that there was a progressive decrease in the specific activity of RNA during treatment, a decrease that was more pronounced initially for vincristine than for vinblastine, as would be expected in view of the greater neurotoxicity produced by the former drug. The results after 21 days are scarcely significant, in view of the low survival rate and moribund condition of the mice. After 7 days of intraperitoneal treatment with vincristine the dose response curve of Fig. 2 was obtained. When RNA was isolated by phenol extraction<sup>13</sup>, rather than by alkaline hydrolysis, and the ribosomal and soluble RNA were separated by precipitation with lithium chloride<sup>14</sup>, the data shown in Table 1 were obtained. Reductions in the specific activity of all RNA fractions were produced by treatment with vincristine, although soluble RNA seemed to be the least sensitive, contrary to the situation in Ehrlich ascites carcinoma cells<sup>14</sup>. This depression in the synthesis of RNA could not be produced by incubating

Table 1. EFFECTS OF VINCRISTINE, AFTER SEVEN DAILY INTRAPERITONEAL INJECTIONS, ON THE SYNTHESIS OF SUBFRACTIONS OF RNA

Fraction	Specific activity (c.p.m./absorbance unit)	
	Control	Vincristine (0.5 mg/kg $\times$ 7)
Interfacial	96.2	14.2
Soluble	14.2	8.9
Ribosomal	42.8	19.8

Fig. 1. The depression of RNA synthesis in mouse brain produced by daily intraperitoneal injections of vincristine ( $\Delta$ ) or vinblastine ( $\circ$ ). The drugs were given in a dose of 0.3 mg/kg. Results are normalized to a 100 per cent control shown with the range of its standard error.

Fig. 2. The dose response curve for the depression of incorporation of tritiated uridine into mouse brain RNA by seven daily intraperitoneal injections of vincristine.

normal brain slices in Eagle's medium in the presence of vincristine and tritiated uridine.

Despite these effects on the synthesis of RNA, that of protein, as measured by incorporation of valine- $1-^{14}\text{C}$ , was not significantly changed after treatment for 7 days with vinblastine or vincristine (0.5 mg/kg).

Further investigations into the effects of the vinca alkaloids on various metabolic pathways in the brain are in progress. The early depression of RNA synthesis during treatment with the relatively more neurotoxic agent vincristine does suggest, however, that this is a factor involved in the development of neuropathy.

## Synthesis of Ribonucleic Acid and Histone Change during Spermatogenesis in the Grasshopper *Chortophaga viridifasciata*

BLOCH<sup>1</sup> showed that different nuclei of a tissue react differently when the tissue is stained with a mixture of fast green and eosin. He found that fast green has a higher affinity for histones rich in arginine, and eosin for histones rich in lysine, and that in some cell types cessation or slowing of the synthesis of RNA is associated with acquisition of an eosinophilic histone.

We have investigated the correlation between the synthesis of RNA and changes in the reaction to staining with fast green and eosin in spermatids of *Chortophaga viridifasciata*.

Nymphs of grasshoppers collected in Austin, Texas, between October 1965 and April 1966 were injected with 6  $\mu\text{c}$ . of uridine labelled with tritium (specific activity 1.15 c./mmole) and killed 5 or 6 h after injection. The testes were fixed in 10 per cent neutral buffered formalin, dehydrated, embedded in paraffin and sectioned at 10 $\mu$ . The sections were mounted on slides and autoradiographed using Kodak 'AR-10' fine grain scientific plates<sup>2</sup>. The autoradiographs were exposed for 9 days and developed. After development the sections were stained with toluidine blue (0.1 per cent solution buffered at pH 4.1 with acetate buffer) following the method of Prescott and Bender<sup>3</sup>. Grain counts were made of at least twenty individual nuclei in cells in each of eight stages of spermiogenesis taken from cysts in each of four different tubules. We considered only those nuclei the cut surface of which faced the emulsion. The following formula was used to correct for background

$$N = \left( \frac{N_{\text{obs}}}{A} - \frac{N_{\text{bg}}}{A_{\text{bg}}} \right) \bar{A}$$

where  $N_{\text{obs}}$  is the observed number of grains in a nucleus,  $\bar{A}$  is the average area of the nuclei at that stage,  $N_{\text{bg}}/A_{\text{bg}}$  is the average number of grains per unit area of background, and  $N$  is the number of grains in a nucleus, corrected for background. The corrected mean number of grains/area and standard error were calculated for each stage. This value was used as a measure of RNA synthesis. The areas were measured in arbitrary units.

The grasshopper tissue used for staining with fast green and eosin was fixed in 10 per cent neutral buffered formalin, dehydrated, embedded in paraffin and sectioned. The tissue was stained with fast green and eosin according to Bloch<sup>1</sup>, and absorption measurements were made with a microspectrophotometer<sup>4</sup>. Measurements at wavelengths of 640 and 500 m $\mu$  were made of at least twenty cells in each of the designated stages of spermiogenesis. The ratios of extinctions at 500 m $\mu$  and 640 m $\mu$  were determined for each cell, and the mean  $E_{500}/E_{640}$  and the standard error were determined for each stage. A high ratio of  $E_{500}/E_{640}$  is indicative of the presence of the eosinophilic histone (see Fig. 1).

The changes which occur before and during meiosis have been described in detail<sup>5</sup> and were divided into only two comprehensive stages for the purposes of this investigation. The first stage,  $S_a$ , includes spermatocytes in the diffuse prophase stages. The second stage,  $S_b$ , includes spermatocytes in metaphase, anaphase and telophase. The chromatin material in  $S_a$  cells is dispersed, whereas in  $S_b$  cells it is highly condensed. Spermatid development was divided into eight stages on the basis of changes in morphology (Fig. 2).

A striking negative correlation between RNA synthesis and eosinophilia during spermiogenesis is shown in Fig. 2. Intense RNA synthesis, as indicated by grain counts, occurs in the cells which appear to be devoid of the eosinophilic histone (as indicated by a low  $E_{500}/E_{640}$  ratio).

Fig. 1. Absorption spectrum of a nucleus stained with fast green and eosin. The peak to the left is caused primarily by absorption by the eosin, and that on the right, exclusively by fast green.

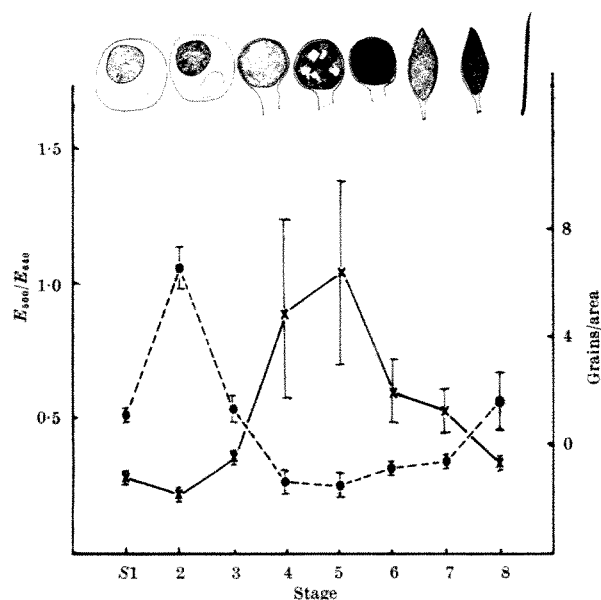

Fig. 2. Comparison of staining and incorporation of uridine into RNA of the nucleus. ●-●, Incorporation; scale at right. x-x, Ratio of  $E_{500}/E_{440}$ , scale at left. The vertical lines show standard errors. The abscissa shows the developmental stages, depicted schematically above the graph.

Decline in RNA synthesis during meiotic chromosome condensation and during the later spermatid stages is accompanied by an increase in eosinophilia and a masking of the fast green staining.

The nature of the eosinophilic protein is not known. It is probably a histone because it is a basic nuclear protein which requires the removal of DNA before staining. In several model systems, it has been shown that eosin successfully competes with fast green in staining proteins that are rich in lysine, and for this reason it is probable that the eosinophilic protein is a histone rich in lysine. Bloch<sup>1</sup> also found that the eosino-

philic histone, when it does occur in cells, does not replace the other histone but merely masks its staining with fast green. The eosinophilic histone may play the part of a non-specific regulator of synthesis of the RNA in the nucleus as a whole.

Such "repression" by histones has been well established in *in vitro* systems<sup>6</sup>, and lysine histones appear to be among the most effective inhibitors of RNA synthesis<sup>7</sup>. These proteins have also been implicated in the control of *in vivo* systems<sup>1,8</sup>. It is perhaps significant that in these two cases control was observed as a nuclear or cellular rather than as a genic phenomenon.

We thank Professor Walter V. Brown for his interest and encouragement and Miss Carol Altsuler for illustrating the manuscript. This work was supported in part by grants from the US National Science Foundation, and the US Public Health Service, National Institute of General Medical Sciences.

### Phytohaemagglutinin and Cell Mediated Hypersensitivity Reactions in Rat

PHYTOHAEMAGGLUTININ (PHA) has been used *in vitro* extensively over the past 18 yr<sup>1</sup>. Comparatively few attempts have been made, however, to study its effect *in vivo*<sup>2,3</sup>.

We were impressed by the apparent similarity between the immunological status of patients with Hodgkin's disease, whose lymphocytes show increased DNA synthesis (Crowther, D., personal communication), and the reported *in vitro* action of PHA, which also causes increased DNA synthesis. It was therefore decided to study the effect of *in vivo* PHA on a delayed hypersensitivity reaction in the rat to see if the non-specific stimulation could result in impaired hypersensitivity reactions.

In the present series of experiments, cutaneous hypersensitivity to pertussis vaccine in the rat was used as a test system<sup>4</sup>. Two types of PHA were used in these experiments (Difco<sup>M</sup> and Wellcome<sup>M</sup>); there was no detectable difference in effect between the two types. PHA was administered intravenously in a dose of 0.5 ml. (reconstituted)/200 g body weight. In the first series of experiments, PHA was given 24 h before the primary injection, then daily throughout the 12 day period of sensitization and once after challenge. This procedure led to a 58 per cent suppression of the inflammatory reaction (which consisted of swelling of the foot) 24 h after the challenge and 76 per cent suppression of the reaction 48 h after challenge (Table 1). To investigate the possibility that the PHA might be acting as an anti-inflammatory agent, rats were given a single dose of PHA before the production of a pleurisy induced by turpentine<sup>10</sup>. This treatment failed to affect the development of the exudate. Similarly, rats on a 12 day course of daily

Table 1. CORRELATION OF COLOUR, RELATIVE ABSORPTIONS BY EOSIN AND FAST GREEN, AND URIDINE INCORPORATION BY PRIMARY SPERMATOCYTES IN THE DIFFUSE AND CONDENSED MEIOTIC STAGES

Stage	Colour	$E_{500}/E_{440}$	Incorporation
Diffuse prophase	Green	$0.20 \pm 0.01$	High
Condensed meiotic	Purple	$1.32 \pm 0.02$	None

This pattern of events is similar to that observed in another system, the developing erythrocyte, in which enhancement of eosinophilia also accompanies the depression of RNA synthesis<sup>5</sup>.

Table 1. EFFECT OF VARIOUS TREATMENTS WITH PHA ON CUTANEOUS HYPERSENSITIVITY TO PERTUSSIS VACCINE IN THE RAT AND ITS EFFECT ON ACUTE INFLAMMATION

Treatment with PHA	Per cent suppression	
	24 h	48 h
Day before primary then daily up to challenge dose + 1 day	58	76
For 5 days daily before primary dose, then no more	58	72.8
For 3 days daily before challenge dose	0	0
Turpentine pleurisy	6 h	
Single dose before acute inflammation	0	
Twelve daily injections before acute inflammation	0	

injections of PHA also responded with normal acute inflammatory reactions in response to intrapleural turpentine. It thus appeared that the PHA did not act as a general anti-inflammatory agent.

Groups of rats were then treated for 5 days with daily intravenous injections of PHA before the primary injection of pertussis. Twelve days after the primary injection they were challenged and showed markedly reduced inflammatory responses. At 24 h there was again 58 per cent suppression and at 48 h a 73 per cent suppression of the reaction.

Finally, rats were given three daily injections of PHA immediately before the administration of the challenging dose of pertussis. This procedure failed to cause any suppression of the reaction.

From these observations it would seem that PHA given before the initial exposure to antigen will suppress the delayed hypersensitivity reaction. On the other hand, PHA given before the challenging dose of antigen fails to reduce the reaction. In addition, PHA does not owe its activity to a general anti-inflammatory action.

It seems possible that the PHA acts by causing a stimulation of the non-committed clones of immunologically competent cells, thus rendering them unable to respond for that period to antigenic stimulation of the type administered.

## Hydroxyproline Indices

WHEN it was known that the excretion of hydroxyproline peptides in the urine was correlated with active growth, and varied in a characteristic way with age<sup>1-3</sup>, Alison *et al.*<sup>4</sup> demonstrated that as a measure of growth the ratio of hydroxyproline : creatinine in a 24 h collection of urine was a great improvement on the hydroxyproline excretion/24 h, because the former eliminated to a great extent the effects of weight, and gave more consistent results for subjects of the same age. They found that the ratio fell in children between 1 and 5 yr, and then remained constant until puberty, after which it fell again to the adult level. Jasin *et al.*<sup>1</sup> had already introduced the factor of surface area to try to eliminate the effects of size, and had found that the results obtained were constant between the ages of 1 and 10 yr.

Whitehead<sup>5,6</sup>, wishing to use random samples of urine for his work rather than 24 h collections, and not knowing the exact ages of the children in which he was interested, (a) satisfied himself of the constancy of the ratio of hydroxyproline : creatinine during 24 h by testing many random samples from the same individuals, and (b) added the parameter of weight to the ratio of hydroxyproline : creatinine, and developed what he called the hydroxyproline "index" as a measure of marginal malnutrition and of a failure to grow. This index had the same advantage that the hydroxyproline excretion/m<sup>2</sup>/24 h would have had in giving a constant figure for the age range in which he was interested. It has subsequently been realized that this "constancy" in a given range of weights is empirical, and may only hold for man. There is no such constancy in rats<sup>7</sup>.

Table 1. HYDROXYPROLINE INDICES BASED ON HEIGHT AND WEIGHT IN 103 NORMAL CHILDREN

No. of children	Age (months)	Hydroxyproline ( $\mu$ m)/creatinine ( $\mu$ m)	Weight index		Height index
			Weight measured in individuals	Weight from tables	
20	1-6	0.59	3.6	3.6	33
23	7-12	0.38	3.1	3.4	26
17	13-24	0.27	2.7	2.8	22
6	25-36	0.22	2.6	2.7	20
21	37-48	0.18	2.7	2.6	18
22	49-72	0.19	3.3	3.3	20

Work now in progress had led us to examine parameters other than weight, which might be incorporated into an index to make it valuable in scientific studies of animal growth as well as in clinical medicine. Height appears to be a satisfactory one. Table 1 shows a comparison of the "index" based on weight, with a corresponding one based on height. The methods used were those described by Howells and Whitehead<sup>8</sup>. The weights of the individual children were all known, and the first figures given for the weight index were obtained by averaging the results for each individual child in the group. The height indices for children up to 3 yr were obtained in the same way. The second figures given for the weight index were obtained from tables<sup>9</sup> and the results were much the same. The heights of children of more than 3 yr were not always known, and the figures given for their height indices were obtained only from the tables. Two points are clear: (a) an index based on height changes with age like the one on weight, and (b) that, if a constant value is desirable between 1 and 6, height has a claim to a place in the index as good as or better than weight.

The use of a height rather than a weight index nullifies one criticism of Whitehead's work made by Anasuya and Narasinga Rao<sup>10</sup>, namely, that the improvement in the index during the treatment of malnutrition was caused by the simultaneous changes in weight, and not by an increase in the excretion of hydroxyproline. In a study of forty-eight children by the index based on height, we have obtained the following results. Index on admission was  $13.5 \pm 6.7$  and index on discharge was  $21.5 \pm 8.0$ .

## Antimitotic Activity of a Steroid Guanyl-hydrazone

I HAVE previously shown that a guanylhyazone derivative of a known steroid molecule is a powerful antimitotic agent<sup>1</sup>. This compound, the structure of which is shown in Fig. 1, is 3-guanyl-hydrazone-androstan-17-ol; it is listed by the Italian pharmaceutical house Vister as 2052 V (Fig. 1).

Fig. 1. 2052 V, 3-guanyl-hydrazone-androstan-17-ol

The present investigations were made in order to characterize the antimitotic activity of 2052 V, *in vitro* (in human amnion cell lines and primary kidney cell cultures of pigs and hamsters) and *in vivo* (in mice and hamsters).

Human amnion cell cultures (H. A. Mascoli's line), propagated *in vitro* in Hanks medium, supplemented with lactalbumin hydrolysate and 5 per cent calf serum, were collected by trypsinization from cultures which had been stationary for 36 h, dispersed in the same medium (300,000 cells/ml.) and seeded on coverslips which had been placed on the bottom of Petri dishes; at the same time either 2052 V (1 and 10  $\mu\text{g}/\text{ml.}$ ) or colchicine (1  $\mu\text{g}/\text{ml.}$ ) were added. Untreated cultures were kept as controls. At intervals of 12, 24, 36 and 48 h the coverslips were fixed in methanol and stained with Giemsa. Mitotic figures were registered and the mitotic index calculated.

Table 1. ANTIMITOTIC ACTIVITY OF 2052 V IN COMPARISON WITH THAT OF COLCHICINE ON HUMAN AMNION CELL CULTURES

Percentage of mitotic figures and mitotic index (M.I.) in cell cultures at different times after treatment.

h	No treatment				2052 V (1 $\mu\text{g}/\text{ml.}$ )				Colchicine (1 $\mu\text{g}/\text{ml.}$ )			
	M.I.	P	M	A	M.I.	P	M	A	M.I.	P	M	A
12	2.5	32	40	8	20	14.8	2	98	—	—	—	—
24	2.8	25	34	11	30	46.0	—	100	—	—	—	—
36	2.3	16	49	11	24	12.8	—	98	1	1	27.6	—
48	2.1	15	51	9	25	4.0	—	100	—	—	15.0	—

P, Prophase; M, metaphase; A, anaphase; T, telophase.

This is a typical experiment representative of many other experiments.

2052 V produces an effect like that of colchicine (Table 1); at a concentration of 1  $\mu\text{g}/\text{ml.}$  it produces a complete mitotic block in metaphase, as shown by the disappearance of anaphases and telophases and by the increase of abnormal metaphases. The mitotic index declines faster with 2052 V than with colchicine because metaphases arrested by the former compound degenerate more rapidly, and because a few cells may break through the 2052 V block. At a concentration of 10  $\mu\text{g}/\text{ml.}$  of 2052 V a clear cytotoxic effect is present within 24 h. In cultures treated with 2052 V, cells in inter-kinesis display nuclear budding which leads to polynucleated cells. This process becomes evident after 12 h of treatment and affects a progressively larger number of cells.

In order to evaluate further analogies between 2052 V and colchicine other experiments have been carried out on primary kidney cell cultures of pigs and hamsters. It is known that hamster cells are resistant to the antimitotic activity of colchicine *in vivo*<sup>2,3</sup> and *in vitro*<sup>3</sup>. Either 2052 V or colchicine was added to the culture medium at a concentration of 1  $\mu\text{g}/\text{ml.}$  Twenty-four hours later mitotic figures were registered and the mitotic

index was calculated. Untreated cultures were kept as controls.

As may be seen in Table 2, the kidney cells of pigs are inhibited both by colchicine and by 2052 V while the kidney cells of the hamster are resistant to the antimitotic activity of both compounds.

Table 2. INFLUENCE OF 2052 V AND COLCHICINE ON PRIMARY KIDNEY CELL CULTURES OF PIG AND HAMSTER

Percentage of mitotic figures and mitotic index (M.I.) in cell cultures after 24 h of treatment

Treatment	M.I.	Pig				M.I.	Hamster			
		P	M	A	T		P	M	A	T
No treatment	1.6	31	42	12	15	1.2	28	42	7	23
2052 V (1 $\mu\text{g}/\text{ml.}$ )	2.9	—	100	—	—	1.0	20	50	10	20
Colchicine (1 $\mu\text{g}/\text{ml.}$ )	3.6	2	97	1	—	1.2	17	69	4	10

2052 V was administered intraperitoneally to mice and hamsters in single doses of 10, 25, 50 or 100 mg/kg. Other animals were given colchicine 10 mg/kg intraperitoneally. The animals were killed 8 and 30 h after treatment, bone marrow mitotic stages were registered and mitotic indices calculated.

Table 3. INFLUENCE OF 2052 V (100 MG/KG INTRAPERITONEALLY) AND COLCHICINE (10 MG/KG INTRAPERITONEALLY) ON BONE MARROW MITOSES OF MOUSE AND HAMSTER

Percentage of mitotic figures and mitotic index (M.I.) in bone marrow cells at different times after treatment. Percentage calculated on the basis of at least three animals.

Treatment	h	M.I.	Mouse				M.I.	Hamster			
			P	M	A	T		P	M	A	T
No treatment	—	0.8	20	40	10	30	0.9	9	47	18	26
2052 V	8	2.4	—	95	—	5	0.9	10	45	15	30
2052 V	30	1.6	20	60	5	15	0.7	5	45	20	30
Colchicine	8	6.6	—	100	—	—	1.5	3	63	13	21
Colchicine	30	5.3	—	95	—	5	1.3	5	50	15	30

The most significant results obtained are reported in Table 3. In mice, 2052 V in doses of 100 mg/kg caused a nearly complete disappearance of ana-telophases at 8 h, and also caused a rise of mitotic index from 0.8 to 2.4 per cent. After 30 h these effects regressed. Single doses of 10, 25 and 50 mg/kg were less effective. Colchicine at the dose of 10 mg/kg was more effective than 100 mg/kg of 2052 V and its blockade was more persistent.

In hamsters, unlike mice, both 2052 V and colchicine failed to affect mitoses significantly.

In conclusion, 2052 V is a mitotic poison both *in vitro* and *in vivo*. It shows several analogies with colchicine and griseofulvin. In fact, all three compounds produce a block in metaphase; moreover, like colchicine<sup>2,3</sup> and griseofulvin<sup>7</sup>, 2052 V is ineffective in hamsters both *in vivo* and *in vitro*. The similarity between griseofulvin and 2052 V is more marked because this compound produces nuclear buddings which are identical to those seen with griseofulvin<sup>4-6</sup>. 2052 V is effective *in vitro* at concentrations as low as those of colchicine; however, *in vivo* doses greater than those for colchicine are needed to produce the same effect. Also *in vivo* metaphasic blockade by 2052 V is less persistent than that by colchicine.

2052 V is of great interest because it is the only known steroid molecule endowed with antimitotic activity similar to that of colchicine. The resistance of hamsters to colchicine, griseofulvin and 2052 V suggests that, despite the differences in structure, 2052 V also acts as a mitotic spindle poison.

### Effect of Azide and Oligomycin on the Transport of Calcium Ions in Corn Mitochondria

INHIBITION of respiration by azide has been known for many years. It is now generally considered that azide not only inhibits electron transfer through the cytochrome chain, presumably by inhibiting cytochrome oxidase<sup>1,2</sup>, but that it also inhibits one of the associated reactions involved in the production of ATP (refs. 3 and 4). The reactions of phosphorylation seem to be more sensitive to azide than the electron transfer reactions because smaller concentrations of azide are required to inhibit oxygen uptake in the presence of ADP and inorganic phosphate than in their absence<sup>5,6</sup>, that is, state 3 respiration is more sensitive to azide than state 4 respiration.

The effect of azide on the partial reactions of phosphorylation, that is, the ATPase, the ATP-Pi and ATP-ADP exchange reactions, appear to be similar to that of oligomycin<sup>7-10</sup>. Wadkins and Lehninger<sup>9</sup> suggested that both azide and oligomycin function by combining with a non-phosphorylated intermediate, thereby preventing formation of any phosphorylated intermediates. Lardy *et al.*<sup>10</sup>, working with rat liver mitochondria, as well as ourselves working with corn shoot mitochondria<sup>11,12</sup>, have suggested that oligomycin blocks after the entry of inorganic phosphate into organic combination. In further comparing the effects of azide and oligomycin on the transport of calcium ions in corn mitochondria we have found that both inhibitors behave similarly, with one important exception, the ADP impairment of substrate-driven transport of calcium ions is alleviated by oligomycin but not by azide. These results indicate separate sites of action of azide and oligomycin on the phosphorylation reactions and are interpreted accordingly.

Corn (*Zea mays*) shoot mitochondria were used in all experiments. The isolation procedure and experimental techniques were essentially as previously described<sup>11</sup>. Uptake of calcium ions was followed using calcium-45. Incubations were carried out in 'Pyrex' centrifuge tubes at 30° C. After incubation the mitochondria were re-isolated by layering the incubation mixture over 2.5 ml. of 0.5 molar sucrose and centrifuging at 0° C. Mitochondrial pellets were suspended in water and counted for radioactivity. Oligomycin was obtained from Sigma Chemical Company, St. Louis, and its molarity was calculated on the basis of 15 per cent oligomycin A and 85 per cent oligomycin B.

Table 1. GENERAL CHARACTERISTICS OF ACCUMULATION OF CALCIUM IONS BY MAIZE MITOCHONDRIA

Experiment No.	Treatment	Accumulation of calcium ions $\mu\text{moles/mg N/2 min}$
1	Blank	0.36
	Substrate	3.10
	Substrate + ADP ( $10^{-3}$ molar)	1.09
	Substrate + oligomycin ( $10^{-6}$ molar)	3.38
	Substrate + azide ( $10^{-5}$ molar)	3.10
2	Blank	$\mu\text{moles/mg N/10 min}$ 0.17
	ATP	0.70
	ATP + oligomycin ( $10^{-6}$ molar)	0.21
	ATP + azide ( $10^{-5}$ molar)	0.37

The assay medium consisted of 650  $\mu\text{moles}$  sucrose, 17  $\mu\text{moles}$  of inorganic phosphate, 0.5  $\mu\text{moles}$  of calcium chloride (250 c.p.m. of calcium-45/ $\mu\text{moles}$ ), 0.2 mg of mitochondrial nitrogen and substrate (10  $\mu\text{moles}$  of potassium pyruvate and 10  $\mu\text{moles}$  of succinate) or 3.25  $\mu\text{moles}$  of ATP where indicated. Experiment 2 also contained 7.5  $\mu\text{moles}$  of magnesium chloride, pH adjusted to 7.5 with *tris*. The final volume was 2.5 ml.

Higher plant mitochondria accumulate calcium and magnesium ions and inorganic phosphate<sup>11</sup> in a fashion very similar to that reported for mammalian mitochondria<sup>13</sup>. Table 1 illustrates that either oxidizable substrate or ATP can serve as an energy source for the transport of calcium ions. Substrate oxidation is, however, considerably more effective than ATP. This is due in part to the competition with magnesium ions as evidenced by the lower blank values. Oligomycin at  $10^{-6}$  molar has little effect on substrate-driven transport but essentially eliminates ATP-driven transport of calcium ions (92.5 per cent inhibition of net absorption of calcium ions). The inclusion of ADP impairs substrate driven transport of calcium ions and this impairment has previously been shown to be partially relieved by oligomycin<sup>11</sup>. These results are similar to those reported for animal mitochondria and are thus consistent with the hypothesis that a common high energy intermediate of oxidative phosphorylation provides the energy for either calcium ion transport or ATP formation in plant, as well as animal, mitochondria. In our experiments with corn mitochondria, a small but reproducible substrate-dependent binding of calcium ions occurs in the absence of inorganic phosphate, but for transport to be significant the phosphate is essential. Other anions such as acetate or arsenate<sup>11,14</sup> will not substitute for inorganic phosphate, and so it appears that a phosphorylated intermediate is involved in the transport of calcium ions.

Table 1 shows that  $10^{-5}$  molar sodium azide does not inhibit substrate-driven transport of calcium ions, but does partially inhibit ATP-driven transport (62.5 per cent

Fig. 1. The effect of oligomycin (a) and azide (b) on substrate- and ATP-driven accumulation of calcium ions in maize mitochondria. Experimental conditions the same as in Table 1 and text.

Fig. 2. The effect of azide and oligomycin on uptake of calcium ions in the presence of both substrate and ADP ( $8 \times 10^{-4}$  molar). Experimental conditions same as in Table 1 and text.

inhibition of net absorption of calcium ions). Thus azide and oligomycin seem to have similar effects on the two systems of transport of calcium ions.

The relative effectiveness of azide and oligomycin on both the substrate- and ATP-driven transport systems for calcium ions is shown in Fig. 1a and b. Up to about  $10^{-6}$  molar, oligomycin has no effect on substrate-driven transport (Fig. 1a), but at greater concentrations it becomes a potent inhibitor. Half-maximal inhibition occurs at about 30  $\mu$ molar. As is to be expected from Table 1, the ATP-driven transport system for calcium ions is much more sensitive to oligomycin. Half-maximal inhibition in this case is at about 0.5  $\mu$ molar. The inhibition of the substrate-driven system at high concentrations may indicate that oligomycin has a secondary effect on electron transfer. Azide has practically no effect on substrate-driven transport of calcium ions until concentrations greater than  $10^{-4}$  molar are used (Fig. 1b). On the other hand, the system driven by ATP is quite sensitive to azide. The half-maximal inhibitions for the substrate- and ATP-driven systems occur at approximately 700 and 8  $\mu$ molar, respectively. These results, like those of Lehninger and Gregg<sup>5</sup> and Wilson and Chance<sup>6</sup>, suggest that electron transfer (that is, substrate-driven transport in this case) is much less sensitive to azide than is the formation or utilization of high energy intermediates (that is, ATP-driven transport).

Except for the fact that oligomycin is effective at much smaller concentrations, these results do not indicate any differences in function of azide and oligomycin. The results shown in Fig. 2, however, clearly indicate these inhibitors behave differently. In this experiment, substrate-driven transport of calcium ions was investigated in the presence of ADP. The impairment of transport of calcium ions caused by ADP (see also Table 1) is presumably caused by a competition for a common intermediate involved in both the transport of calcium ions and ATP formation. Previous studies had shown oligomycin to relieve this ADP impairment of calcium ion transport<sup>11</sup> by apparently blocking the transfer of phosphate from a phosphorylated intermediate to ADP. This reversal of the ADP impairment is illustrated in Fig. 2 with the optimal oligomycin concentration being about  $10^{-6}$  molar. The fact that the reversal is not complete may be caused by some binding of exogenous calcium ions by the ADP. In contrast to oligomycin, azide does not alleviate the ADP impairment of substrate-driven transport of calcium ions. This must mean that even in

the presence of azide ADP is still effective in competing for the intermediate involved in the transport. (The inhibitions observed with high concentrations of both inhibitors are similar to those shown in Fig. 1a and b for the substrate-driven system and must be the result of secondary effects. In separate but identical experiments, azide was shown to have no effect on oxygen consumption until concentrations greater than  $10^{-4}$  molar were used.) The different effects of azide and oligomycin may be explained according to the diagram shown in Fig. 3, which is a slight modification of an earlier scheme<sup>11,15</sup>. The various high energy intermediates are denoted as modifications of a single moiety (presumably a protein) with two functional groups, I and X. Details of the initial coupling to electron transport are not shown but it appears to involve at least two non-phosphorylated intermediates<sup>14,16</sup>. The initial phosphorylated intermediate

( $\bar{I} \bar{X} \sim P$ ) is considered to be the reactive form involved in the transport of calcium ions in plant mitochondria (see review by Hanson and Hodges<sup>16</sup>). Assuming this to be the case, then both oligomycin and azide must function beyond  $\bar{I} \bar{X} \sim P$ , because substrate-driven calcium ion transport is not inhibited while ATP-driven transport is blocked. The fact that oligomycin will alleviate the ADP impairment of substrate-driven calcium ion transport must mean that ADP can no longer effectively

compete for  $\bar{I} \bar{X} \sim P$  in these conditions and therefore must be acting before the entry of ADP into the system. Azide does not prevent the ADP impairment of substrate-driven transport of calcium ions, and so this inhibitor must be acting beyond the entry of ADP. This is depicted in Fig. 3 by including a phosphorylated-ADP intermediate. In order for ADP to remain effective in restricting transport of calcium ions in the presence of azide, the ADP must be continually recycled, indicating that the phosphorylated-ADP intermediate must be relatively unstable in the presence of azide. The reason for this instability in the presence of azide is not clear to us but it must pertain only to the ADP linkage to the intermediate (that is, not the phosphorylated part of the intermediate), otherwise azide would act as an uncoupler of oxidative phosphorylation instead of an inhibitor of oxidative phosphorylation<sup>17</sup>.

These findings, which implicate separate sites of action of azide and oligomycin, should be of value in further attempts at elucidating the exact mechanism of oxidative

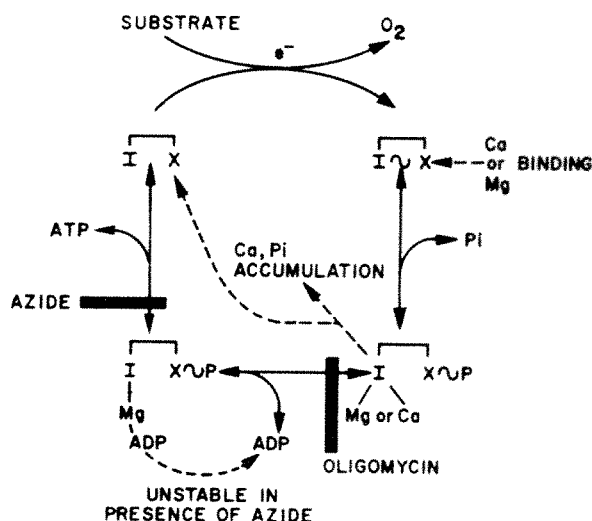

Fig. 3. A scheme depicting possible high energy intermediates of oxidative phosphorylation and suggested sites of action of oligomycin and azide.

phosphorylation and other energy linked functions of mitochondria.

### Photodynamic Activity of 4-Nitroquinoline-1-oxide and Related Compounds

4-NITROQUINOLINE-1-OXIDE (4-NQO) is a potent water-soluble carcinogen the properties of which include phage induction<sup>1</sup>, mutagenicity<sup>2</sup>, high toxicity to single cell systems<sup>3</sup>, malignant transformation<sup>4</sup> and production of nuclear inclusion bodies and chromosomal aberrations in mammalian cells in tissue culture<sup>5,6</sup>. It also binds to DNA<sup>7,8</sup>. We have now also demonstrated photodynamic activity in 4-NQO and related compounds. Photodynamic activity may be defined as a phenomenon dependent on oxygen, in which a combination of light energy and chemical sensitizer produces effects induced by neither component alone<sup>9</sup>.

Stock solutions of 4-NQO and of thirteen related compounds, nitroquinolines and hydroxyaminoquinolines (Table 1), were prepared freshly for each experiment at 1 mg/ml. concentrations in acetone or 95 per cent ethanol. Serial doubling dilutions of fresh aqueous suspensions were prepared over a range from 100 to 3.125 µg/ml. by standardized procedures<sup>9</sup>. Suspensions of compounds and *Paramecium caudatum*, cultured axenically in semi-defined medium of low protein concentration, were incubated in the dark at 28° C for 1 h in multiple depression plastic trays. As a standard, aqueous suspensions of benzo[a]pyrene, prepared by serial doubling dilutions over a range from 1 to 0.0625 µg/ml., were simultaneously tested, together with three compounds on the same tray. The trays were then irradiated with long wave ultra-violet light with a narrow peak at 3660 Å from two 15 W tubes at an intensity of about 6,500 µW/cm<sup>2</sup> at 15 cm and a 108° beam. The time taken for the radiation to immobilize and kill 90 per cent of the motile cells (*LT*<sub>90</sub>) was determined by observation with a stereoscopic microscope and an arbitrary observational limit of 60 min. Compounds were assayed in duplicate on at least three independent occasions. Under these conditions, high photodynamic activity was manifest by *LT*<sub>90</sub> > 60. By plotting *LT*<sub>90</sub> values against concentrations of the photosensitizing compounds, the concentrations producing *LT*<sub>90</sub> values at 30 min were determined by interpolation. Reciprocals of

these concentrations provide a scale of photodynamic potency<sup>9</sup>.

While under the condition of assay the hydroxyaminoquinolines are devoid of photodynamic activity, activity of nitroquinolines spans a 3-log range. The activity of the nitroquinolines as a class is weak, however, in comparison with benzo[a]pyrene (Table 1). As both hydroxyaminoquinolines and nitroquinolines absorb similarly in the long wave ultra-violet<sup>10</sup>, other factors must account for the marked differences in the photodynamic activity of these compounds.

Table 1. PHOTODYNAMIC ACTIVITY, FREE RADICAL FORMATION AND CARCINOGENICITY OF 4-NITROQUINOLINE-1-OXIDE AND RELATED COMPOUNDS

\* Type a, unpaired electron is localized on ring or nitro-group nitrogen; type b, unpaired electron is delocalized on both nitrogens.

Compounds producing free radicals with delocalized unpaired electrons (Table 1, type b free radicals) or no free radicals after photo-irradiation with ultra-violet or visible light<sup>10</sup>, are usually devoid of photodynamic activity; the exceptions are 4-nitroquinoline and possibly 8-methyl-4-nitroquinoline-1-oxide, the free radical type of which has not yet been determined. Conversely, there is an interesting positive association between photodynamic activity and the formation of free radicals with unpaired electrons localized on ring or nitro-group nitrogen (Table 1, type a free radicals). The further positive association between these two parameters—photodynamic activity and type a free radical formation, and carcinogenicity—is of additional interest in view of the strong positive association existing between photodynamic activity and carcinogenicity in polycyclic compounds<sup>9</sup>.

Perhaps photodynamic activity of the nitroquinoline-1-oxides differs from that of benzo[a]pyrene because free radicals have been detected on photo-irradiation of the nitroquinolines at room temperature<sup>10</sup> and also after photo-irradiation of haematoporphyrin (another photosensitizer<sup>11</sup>) but not benzo[a]pyrene, even at -196° C (J. M. Rice and S. S. Epstein, personal communication). Possibly relevant is the apparent failure of various antioxidants, for example, 4-dimethylaminoazobenzene, α-tocopherol or nordihydroguaiaretic acid, to protect against the photodynamic effects of 4-NQO (S. S. Epstein, personal communication) in contrast to their marked protective effects, presumably by scavenging free-radicals, against polycyclic photosensitizers such as benzo[a]pyrene<sup>12</sup>.

The findings here might suggest that some effects of the nitroquinoline-1-oxides, for example, mutagenesis by 4-NQO<sup>2</sup>, are indirect and incidentally mediated through photodynamic mechanisms. This, however, is unlikely because (with the exception of photodynamic activity) 4-NQO and its reduction product and presumed proximate carcinogen, 4-hydroxyaminoquinoline-1-oxide, have similar biological properties<sup>2</sup>.

We thank Dr Y. Kawazoe for the gift of quinolines, and Drs W. Nakahara and S. H. Hutner for their interest. We thank the World Health Organization and the Children's Cancer Research Foundation, Boston, for support.

## Antigenicity of Mycoplasma Membranes

UNLIKE bacteria, mycoplasmas do not have a rigid cell wall<sup>1,2</sup>, but they are bounded by a triple layered limiting membrane 70–80 Å thick<sup>3</sup>. Immunological reactions with these organisms have been studied by a number of techniques, of which growth inhibition and haemagglutination inhibition are believed to represent reactions with the surface of the organism<sup>4,5</sup>. Whole mycoplasma cells of different species have been chemically fractionated by various workers<sup>4,6–10</sup> and found to contain carbohydrates, proteins and lipids. Studies, particularly on *Mycoplasma pneumoniae*, have shown that most of the antigenic activity is associated with lipids which react with antibody, and when combined with protein stimulate antibody, including growth-inhibiting antibody<sup>4</sup>. It is tempting to believe that these lipids have been extracted from the cell membrane because lipids are an integral part of membranes of many cells. Physical methods have been described for the preparation of isolated membranes from mycoplasmas<sup>11</sup> and we have isolated membranes from the serologically distinct organisms *M. gallisepticum* (S6) and *M. pneumoniae* (FH) and have attempted to stimulate, in particular, growth-inhibiting antibody with them.

The growth medium consisted of Difco PPLO broth containing 20 per cent Burroughs Wellcome No. 6 unheated horse serum, 2.5 per cent D.C.L. yeast extract, 1.0 per cent glucose, 0.002 per cent phenol red, 1:2,000 thallium acetate and 1,000 U of penicillin/ml. To prepare antigens of *M. gallisepticum*, 300 ml. of medium, pH 7.8,

were inoculated with 30 ml. of a culture containing 10<sup>8</sup> or more organisms/ml. and incubated at 36° C for 48 h. At this time the culture medium, pH 6.5, containing 10<sup>9</sup> or more viable organisms/ml., was centrifuged at 10,000g for 10 min; the pellet was resuspended in 10 ml. phosphate-buffered saline (PBS), pH 7.2, and then divided into two equal portions. The first 5 ml. portion was washed once by resuspending in cold, sterile PBS and centrifuging at 10,000g for 10 min. The mycoplasma cells resuspended in 10 ml. of sterile PBS constituted the whole cell antigen. The second 5 ml. portion was diluted to 20 ml. with sterile de-ionized water and this suspension was frozen at –20° C and thawed at room temperature ten times and then centrifuged at 19,000g for 10 min. The supernatant fluid was removed and stored at 4° C and the deposit was resuspended in 20 ml. of water and the freezing-thawing treatment was repeated. This suspension was then centrifuged at 19,000g for 10 min, the small deposit was discarded and the supernatant fluid was pooled with that from the first centrifugation. These pooled supernatant fluids were then centrifuged at 30,000g for 40 min. The deposit resuspended in 10 ml. of PBS constituted the membrane antigen. The 40 ml. of supernatant fluid from the last centrifugation was dialysed at 4° C against polyethylene-glycol until the volume was reduced to 5 ml.; this constituted the cell-content antigen.

In order to prepare antigens of *M. pneumoniae*, this organism was grown according to the method described by Somerson *et al.*<sup>12</sup>. Ten Roux bottles containing 100 ml. of medium were each inoculated with 5 ml. of a culture containing 10<sup>6</sup> or more viable organisms/ml. and incubated at 36° C. After 3 days, when sheets of growth were adherent to the glass, the medium was removed, the sheets washed five times with sterile PBS and scraped into 10 ml. of this saline. Further procedures for antigen preparation were as described.

Samples of cell-membrane and cell-content antigens were stained with 1 per cent phosphotungstic acid and examined by electron microscopy. Whole mycoplasma cells were not observed. In addition, no growth occurred when mycoplasma medium was inoculated with similar samples.

Rabbits were inoculated with the *M. gallisepticum* and *M. pneumoniae* antigens as follows: 1 ml. of antigen homogenized with 1 ml. of complete Freund adjuvant was given intradermally in multiple sites; 3 weeks later 1 ml. of antigen without adjuvant was given intramuscularly in multiple sites. Two weeks after this, that is, at 5 weeks, a sample of serum was taken and 1 week later 1 ml. of antigen was given intravenously. A second sample of serum was taken 1 week later, that is, at 7 weeks.

All the antisera were examined in the metabolic inhibition test<sup>13</sup> with and without the addition of unheated guinea-pig serum at a final concentration of 3 per cent, and, in addition, antisera to *M. gallisepticum* were examined in a micro-haemagglutination-inhibition test<sup>6</sup> with the A5969 strain.

Pre-inoculation rabbit sera at the dilutions tested did not contain antibody. On the other hand, sera from rabbits given whole cell and membrane antigens of *M. gallisepticum* contained antibody measured by both metabolic inhibition and haemagglutination inhibition techniques; the cell-content antigen did not stimulate antibody measurable by either method (Table 1). Com-

Table 1. TITRES OF ANTIBODY AFTER INOCULATION OF RABBITS WITH WHOLE CELL, CELL-MEMBRANE AND CELL-CONTENT ANTIGENS

Membrane	(<20) 320	(<4) 64	(<2) 16	(<2) 16
Cell content	(<4) <4	(4) 4	(<2) <2	(<2) <2

\* Figures in parentheses indicate titres of pre-inoculation sera.  
† 0.5 per cent chicken erythrocytes and four haemagglutinating units of antigen were used.

parable titres were obtained with the 5 and 7 week antisera prepared in two rabbits inoculated with each antigen of *M. gallisepticum*. Furthermore, whole cell and membrane antigens but not cell-content antigen of *M. pneumoniae* stimulated antibody measured by the metabolic inhibition technique. The addition of unheated guinea-pig serum to the metabolic inhibition test did not increase the antibody titres for either *M. gallisepticum* or *M. pneumoniae*. It has been shown previously<sup>13,14</sup> that at the titre end-point in this test there is inhibition of mycoplasma growth. These results agree with the hypothesis that antigens present on the membrane of mycoplasma cells combine at this site with antibody to inhibit growth of the organisms. The exact mechanism of this inhibition is being investigated.

We thank Dr D. Roberts, Central Veterinary Laboratory, Weybridge, for the strains of *M. gallisepticum*, Dr R. Chanock, US National Institutes of Health, Bethesda, Maryland, for the strain of *M. pneumoniae*, and Mrs S. Beveridge for technical assistance.

### Simple Microassay of Protein with Membrane Filter

THE quantity of protein in dilute solution is usually determined by the method of Lowry *et al.*<sup>1</sup>, using phenol reagent. This method is sensitive and simple, but it is applicable only to solutions containing more than 10  $\mu\text{g}/\text{ml}$ . and it suffers from interference by various chemicals. For example, *tris*(hydroxymethyl)aminomethane can react with the reagent to develop an intense colour and in the presence of magnesium ions the phenol reagent forms a precipitate which greatly lessens the strength of the colour. Thus unless freed from these materials the values obtained under these conditions are rather unreliable. Removal of the interfering chemicals cannot be easily performed with dilute protein solutions and is inconvenient if a large number of samples is being analysed. Protein determination by ultra-violet absorbance may also suffer from severe interference by other chemicals. The reading is affected by nucleotides or many

Fig. 1. Quantitative binding of protein on the membrane filter, and quantitative staining with amido black. Samples of 10  $\mu\text{g}/\text{ml}$ . 0.2 molar magnesium chloride solution of each protein were used. The solution was passed through membrane filter which was then washed with 0.2 molar magnesium chloride solution, and protein bound to the membrane filter was stained with amido black. The dye bound to the protein was eluted with 3.5 ml. of 0.01 normal sodium hydroxide and the absorbance of the eluant was determined.  $\Delta$ , Bovine serum albumin;  $\times$ , rat liver soluble fraction;  $\bullet$ , *E. coli* soluble fraction.

other chemicals and the results must be corrected for them<sup>2</sup>.

A previous investigation of purification and classification of RNA phages with the aid of a membrane filter<sup>3,4</sup> (Schleicher B-6 27MM) showed almost quantitative binding of protein to the filter. The extent of this binding varies with salt concentration, and bivalent metal ions like magnesium (II) and calcium (II) are more effective than sodium (I) or potassium (I) ions. On this basis, a simple procedure for microassay of protein was developed, in which the bound protein was stained with amido black and the dye retained on the filter was eluted and measured.

Samples containing 5–50  $\mu\text{g}$  of protein were made 0.2 molar with respect to magnesium chloride. This solution was passed through a membrane filter under reduced pressure. The membrane was washed with 3 ml. of 0.2 molar magnesium chloride and the protein was stained by passing 2 ml. of amido black solution, 4  $\mu\text{g}/\text{ml}$ ., in acetic acid-methanol-water (1:5:4). After washing with 5 ml. of 1 per cent acetic acid solution the bound dye was eluted with 3.5 ml. of 0.01 normal sodium hydroxide. The concentration of the dye in the eluant was measured at 620 m $\mu$ . The quantity of dye bound on the protein is related linearly to the amount of protein applied (see Fig. 1). In this experiment, bovine serum albumin, fraction V (Armour), and the supernatant fractions of rat liver homogenate and *Escherichia coli* B (obtained by ultracentrifugation at 100,000g, 120 min) were used as the protein sample.

To ascertain the completeness of attachment of protein to the membrane filter the filtrate was tested for any unattached protein. Fifty micrograms of albumin in 1.0 ml. of 0.2 molar magnesium chloride were passed through to each membrane filter, and filtrates were combined. The combined filtrate was passed through a new membrane filter and stained for any bound protein as before. The amount of protein which has failed to bind to the initial membrane filter was found to be less than 3 per cent. With this method, solutions of protein with concentration down to 0.3  $\mu\text{g}/\text{ml}$ . gave reliable results providing that the total amount of protein applied to the filter exceeded 10  $\mu\text{g}$ .

Table 1. COMPARISON OF PROTEIN DETERMINATION BY THE PHENOL REAGENT METHOD AND BY THE MEMBRANE FILTER METHOD

Ingredient	Amount of protein observed*	
	By phenol reagent	By membrane filter
None	20.8 ± 0.2	20.0 ± 0.1
Tyrosine 4 µg	20.8* ± 1.2	20.0 ± 0.3
Tris-HCl 0.005 molar	22.1* ± 1.8	19.9 ± 0.1
CMP ‡ 50 µg	21.1 ± 0.5	18.7 ± 0.1

\* Figures are averages of five samples. Each sample contained 20.0 µg of serum albumin.

† Tyrosine and tris-HCl alone gave colour reaction corresponding to 15.8 µg and 21.6 µg of serum albumin respectively. The values shown above were corrected for these figures.

‡ Cytidine monophosphate.

Tests for chemicals which usually interfere in current procedures are summarized in Table 1. The materials which irritated the ultra-violet absorption method and the chemicals which react with phenol reagent showed virtually no interference in our method of assay.

### Inhibition of ADP Phosphorylation by the Atractyloside of Yeast Respiratory Particles

ATRACTYLOSIDE is known to prevent the phosphorylation of exogenous ADP by intact liver mitochondria<sup>1</sup>, and to block the passage of adenine nucleotides across the mitochondrial membrane<sup>2-7</sup>. The question therefore arises as to whether or not these two effects of atractyloside are independent of each other.

An experimental approach to this problem could be made by using yeast respiratory particles (damaged mitochondria prepared by disruption of yeast cells); these particles, in contrast to liver mitochondria, are able to utilize for the substrate-linked phosphorylation not only  $\alpha$ -ketoglutarate, but also acetyl-carnitine<sup>8,9</sup>.

In contrast to liver mitochondria, it is possible to prepare a soluble extract from these particles which is able, like the particles themselves, to utilize acetyl-carnitine in the presence of succinate for ADP phosphorylation<sup>8</sup> through the last steps of the substrate-linked phosphorylation.

The action of atractyloside has been tested on the particulate and the soluble systems. The results are shown in Table 1.

It can be clearly seen that the acetyl-carnitine dependent phosphorylation of ADP is strongly inhibited by atractyloside when catalysed by respiratory particles, while it is completely unaffected in the soluble enzyme system.

These results suggest that an insoluble structure is required before atractyloside can exert its inhibitory effect, and that any specific inhibition by atractyloside on the enzymes involved in the substrate level ADP phosphorylation described can be ruled out.

It is also interesting that arsenate, unlike atractyloside, prevents synthesis of ATP through substrate level phosphorylation, both in the particulate and in the soluble system.

The requirement of an insoluble structure for the inhibitory effect of atractyloside does not necessarily mean that this inhibitor acts by preventing an enzyme translocation of adenine nucleotides from outside to inside the mitochondrial membrane.

Table 1. EFFECT OF ATRACTYLOSIDE ON ATP SYNTHESIS BY YEAST RESPIRATORY PARTICLES AND BY THEIR SOLUBLE EXTRACT IN PRESENCE OF ACETYL-CARNITINE

	ATP (mµmoles) formed	
	Particles	Soluble extract
Acetate + carnitine + succinate	10	99
Acetyl-carnitine + succinate	126	246
Acetyl-carnitine + succinate + atractyloside	43	250

Yeast particles (1 ml., equivalent to 30 mg of protein) were incubated in 2.7 ml. of a medium containing 100 µmoles of tris-hydrochloric acid buffer pH 7.4, 12 µmoles of magnesium chloride, 1 µmole of phosphate, 20 µmoles of substrate, except succinate (10 µmoles) and 30 µmoles of malonate, 0.6 µmoles of atractyloside when present. No ADP or AMP was added. Incubation was for 10 min at 25° C. Concentration of ATP at zero time was 44 mµmoles. Of the reaction mixture 1.5 ml. contained 1 mg of soluble protein, 75 µmoles of tris-hydrochloric acid buffer, pH 7.4, 10 µmoles of substrate, except succinate (5 µmoles), 20 µmoles of magnesium chloride, 0.4 µmoles of coenzyme A, 20 µmoles of phosphate, 2 µmoles of ADP, 80 µmoles of potassium fluoride, 0.3 µmoles of atractyloside when indicated, 100 Kunitz-MacDonald units of hexokinase, and 50 µmoles of glucose. Incubation was for 10 min at 25° C. The soluble extract was prepared at 0° C by mechanical disruption\* of yeast particles with a Virtis homogenizer for 20 min at 20,000 r.p.m. in the presence of 0.2 molar potassium chloride, 0.5 molar EDTA, 50 mmolar potassium phosphate, pH 7.4. After centrifugation for 15 min at 100,000g, the clear supernatant (10 ml.) was passed through a column of 'Sephadex G-25' (1.8 × 26 cm) previously equilibrated with 10 mmolar phosphate, pH 7.5. Proteins were determined by the biuret method modified by Gornall<sup>10</sup>.

As was previously shown, an insoluble mitochondrial structural protein is able to bind adenine nucleotides in a way which is inhibited and reversed by atractyloside<sup>11</sup>.

This observation suggests that the binding of adenine nucleotides to the structural protein may be the preliminary step required for some processes involving adenine nucleotides in intact mitochondria.

### Translocation of DNA of Bacterial Origin in *Lycopersicon esculentum* by Ultracentrifugation in Caesium Chloride Gradient

WE have previously reported<sup>1,2</sup> results showing that exogenous tritiated DNA molecules can migrate in the xylem of tomato plant and, after some degradation, be taken up by the meristematic cells. We now report our investigation of the nature of the radioactive molecules recovered after incubation of the plant by bacterial DNA using ultracentrifugation in a caesium chloride gradient.

We used the tomato variety 'Tuckwood' treated in the following way. Apical shoots (5-9 cm) of adult plants with young leaves and without roots were dipped into a solution of *Escherichia coli* or *Bacillus subtilis* tritiated DNA for 6 h. They were then transferred to water for 48 h. The region dipped in the DNA was removed before

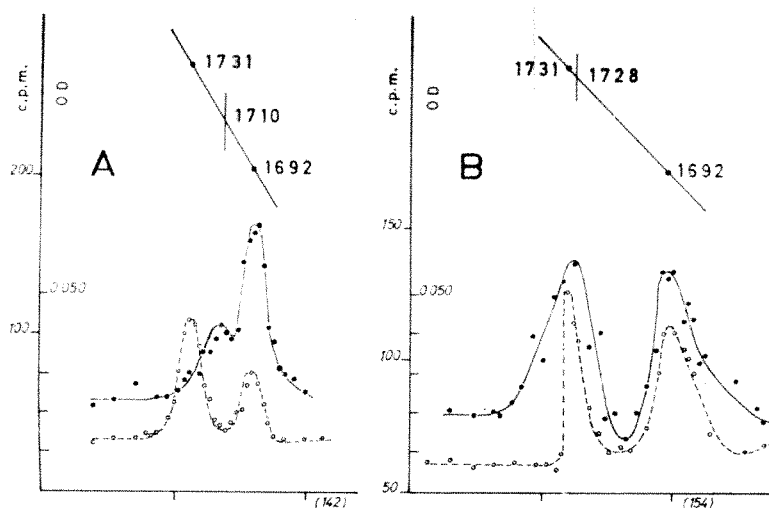

Fig. 1. Caesium chloride ultracentrifugation diagram of the DNA extracted from tomato plants after an incubation of 6 h in presence of bacterial tritiated DNA followed by 48 h in water. A, Plants incubated in presence of *E. coli* tritiated DNA ( $\rho = 1.710$  g/ml.). B, Plants incubated in presence of *B. subtilis*  $D_2O$  tritiated DNA ( $\rho = 1.728$  g/ml.). Broken line: ultra-violet absorption (tomato DNA  $\rho = 1.692$  g/ml.) (*M. lysodeikticus* DNA  $\rho = 1.731$  g/ml.). Continuous line: radioactivity.

homogenization. In order to make sure that no DNA went up the stem by external capillarity, a ring of silicon grease was placed just above the dipped part. When roots were present we obtained results qualitatively similar but quantitatively smaller.

Bacterial DNA was extracted following the method of Marmur<sup>3</sup> from *Escherichia coli* strain CR 34, without thymine and cultured on a medium containing tritiated thymine. The specific activity obtained ranged from  $5 \times 10^5$  d.p.m./ $\mu$ g to  $3 \times 10^6$  d.p.m./ $\mu$ g. We have also used DNA from *Bacillus subtilis*, strain SMYW, type Marburg prototrophic, adapted to  $D_2O$  medium, and cultivated in the presence of tritiated thymidine. In this case the specific activity obtained was about  $2 \times 10^5$  d.p.m./ $\mu$ g. The concentration of the DNA solution used was about 200  $\gamma$ /ml. (similar results are obtained with concentrations ranging from 120  $\gamma$ /ml. to 800  $\gamma$ /ml.).

Plants weighing 0.5 g were cut in small pieces, placed in a 0.025 molar *tris* buffer (pH 7.5), and homogenized for 15 sec in an 'Ultra-Turrax' in the presence of 1 per cent sodium dodecylsulphate (SDS). Two mg/ml. of pronase was added to the solution and it was then incubated for 2 h at 37° C. The mixture was shaken for 15 min with an equal volume of redistilled phenol, saturated with 0.025 molar *tris* solution and adjusted to pH 8. After centrifugation at 1,000g for 10 min the supernatant was precipitated in the cold with 2 vol of ethanol. The 'precipitate' was brought into solution with 2 ml. of diluted saline citrate (0.015 molar sodium chloride and 0.0015 molar sodium citrate). Ribonuclease (100  $\mu$ g) was added for each millilitre of solution, which was incubated for 45 min at 37° C. This step was followed by the addition of 2 mg/ml. of pronase and incubation at 37° C for 1 h. The solution was again treated with 2 vol of alcohol and the insoluble material brought into solution with diluted saline citrate. Caesium chloride was added to the final solution (1.25 g/ml.); 3 ml. of this solution was spun in an 'SW 39' Spinco rotor with 30  $\mu$ g of an unlabelled DNA of *Micrococcus lysodeikticus* ( $\rho = 1.731$  g/ml.) as a reference. After centrifugation (27,000 c.p.m., 62 h, 24° C), the bottom of the tube was punctured and fractions of two drops were collected under constant pressure. One millilitre of water was added to each sample, and the ultra-violet absorption spectrum was recorded on a Beckman 'DK 1' recording spectrometer to determine the position of the *Micrococcus lysodeikticus* reference DNA and the tomato DNA ( $\rho = 1.692$  g/ml.) in the gradient. After hydrolysis with hot 0.1 normal hydrochloric acid the

radioactivity of each sample was measured in a Packard liquid scintillator in presence of a suitable phosphor<sup>4</sup>.

Reference runs were made by adding to the reference samples (*Micrococcus lysodeikticus* DNA and tomato DNA) the bacterial radioactive DNA. Twenty-five experiments were performed with *E. coli* DNA (1.710 g/ml.) or *B. subtilis* deuterated DNA (1.728 g/ml.).

When bacterial DNA is taken up by the plant, the radioactive molecules found in the tomato appear to be distributed into populations having the density of tomato DNA (1.692 g/ml.) and the density of the foreign DNA used (Fig. 1A and B).

In most experiments the amount of radioactivity sedimenting at the level of bacterial DNA is higher than 30 per cent. This indicates that the foreign DNA can be taken up without drastic structural modification. The radioactivity which appears in the position of tomato DNA seems to be that part of the bacterial DNA which has been broken down and reutilized for a synthesis *de novo*.

A previous autoradiographic<sup>2</sup> investigation revealed that when tomato plants were incubated for 6 h with a labelled bacterial DNA and then for 48 h with water, the labelling appeared to be located principally in the nuclei of the cambium cells and of the other meristematic tissues. Our biochemical data imply that part of the labelled molecules found by autoradiography in the cell nuclei are foreign DNA molecules.

Our results show that unlike the situation described in germinating barley seedlings<sup>4,5</sup>, the translocation of DNA is possible not only in the roots but also in the aerial part of the plant. The foreign DNA molecules can migrate in plant tissue and be taken up by cell nuclei without modification of their primary and secondary structures.

## PATHOLOGY

### Possible Dietary Factors in the Aetiology of Chronic Murine Pneumonia, Nephrosis and Peri-arteritis

MOST stocks of laboratory rats are subject to the chronic murine pneumonia described by Nelson and Gowen<sup>1</sup>. Such rats are also prone to a form of peri-arteritis<sup>2</sup> and to nephrosis<sup>3</sup>. All these are diseases of maturity in the rat;

they increase in frequency with age and may, in some cases, affect most old members of a colony. The pneumonia is known to be much less prevalent in wild rats<sup>1</sup>. The aetiology of these diseases is not clear, though in the case of pneumonia Nelson<sup>4</sup> offered evidence that the condition was viral and initiated the development of "specific-pathogen-free" (SPF) animals for colonies free from pneumonia. SPF animals live longer than "dirty" rats. Paget and Lemon<sup>5</sup>, describing such a colony, reported 19 per cent of SPF animals with lungs classified as other than "healthy normal", 12 per cent with severe renal disease and 9 per cent with polyarteritis, as against 96 per cent, 19 per cent and 16 per cent respectively in "dirty" animals.

It therefore seems possible that factors, other than "specific pathogens", may be concerned in the chronic diseases of laboratory rats. Some authors<sup>2,6,7</sup> have remarked on the relation of diet to these diseases; the only pattern which these reports suggested to us is a somewhat lesser incidence of the disease whenever the rats are given a diet reduced in quantity or limited to specific ingredients. This would necessitate a departure from the standard laboratory feeding practices. Worden<sup>8</sup> has commented on the poorer quality of laboratory animals reared on compressed diets since the late 1930s.

In the course of a 2 yr inhalation study in this laboratory, rats have received intermittent minimal exposures to finely particulate beryllium oxide. Initial studies of the Sprague-Dawley strain in use required macroscopic examination of the lungs of more than 100 rats, aged 5-7 months, and microscopic examination of the lungs of thirty; the colony was then thought to be free of murine pneumonia. The rats were kept to the standards recommended by Innes<sup>9</sup>, in wire-bottomed cages in rooms provided with a partly recirculating air-conditioning system.

They were fed an unrestricted commercial cubed diet containing, *inter alia*, dried milk powder and meatmeal.

Mortality has been low and the control groups healthy, except for the development during the growth period of inflamed and sometimes necrotic tails with thinning of hair over face and neck. A similar description attributed to a deficiency of a dietary factor has been given previously<sup>10</sup>. Rats of all groups have been killed at 20 months. At this age control groups showed a high incidence of murine pneumonia with its characteristic peribronchial lymphoid infiltration. Nephrosis was frequent and peri-arteritis was prominent in microscopic sections of the lungs of all groups. Notable microscopic features in the lungs also included foam cells packed with sub-micron Sudan-positive granules, septal cells containing single bodies exhibiting a polarization cross and thought to be lipid droplets, long birefringent fibres, and intra-alveolar crystals or plates brilliantly birefringent in frozen section and sometimes resistant to the solvents of paraffin sectioning.

Another puzzling feature was the apparent contamination of lung sections by dense intra- or extra-cellular particles in a variety of forms, some being naturally black. This led to painstaking rechecking of histological reagents and techniques, without any indication that the particles were artefacts.

Green's<sup>11</sup> illustrations of mouse lung preparations show quite clearly the large crystalline plates and some of the smaller particles that we have seen in rat lungs. She found them to appear in mouse lungs soon after weaning, and subsequently to become more numerous with increasing age.

We have now found that the whole range of particles, including small and large "lipid" droplets, birefringent objects, fibres, and dense particles can be obtained by

Fig. 1. (A) Naturally black object in peribronchial lymphatic tissue (paraffin section). (B) Naturally black object in powdered rat cube. (C) Polarization cross in a cell of alveolar septum (frozen section). (D) Polarization crosses in powdered rat cube—wheat starch granules. Each segment bears a 50 $\mu$  bar.

Fig. 2. (E) Angular plate in alveolus (frozen section). (F) Angular plate in powdered rat cube. (G) Angular plate (E) under polarized light. (H) Precipitin bands of rat serum against powdered coconut meal. Each segment bears a 50 $\mu$  bar.

scrapping a food cube with the points of splinter forceps to simulate the action of the rat's incisors, or by preparing a suspension of crushed cubes. The proportion of very small particles, in the range 0.5–10 $\mu$ , is quite surprising. These findings are evidence of the constant, direct inhalation of food dusts by laboratory rats maintained in conventional conditions. Some of these particles are illustrated in the composite photographs of Figs. 1 and 2.

It is evident that irritation from these particles, which include such foreign proteins as casein and meatmeal, cannot be disregarded in an inhalation study, although Innes<sup>12</sup> has dismissed granulomata from such foreign bodies as clinically silent lesions of the respiratory tract of small animals. Evidence that at least one of the constituents of the food cubes is absorbed and is antigenically active is provided by the precipitin line in Fig. 2, between coconut meal and rat serum. All the rat sera tested showed this reaction. We think it probable that the inhaled particles found in the lungs are at least partly responsible for the appearances of murine pneumonia. Unrecognized inhaled particles may well include matter of fungal or bacterial origin. We cannot do more than speculate on how these particles may be harmful, but it is possible that there is an immunological basis to the disease and that it is akin to bagassosis and, perhaps, the pneumoconioses. If an immunological element is accepted, it is also possible that the renal and arterial lesions found in these rats are of similar origin. If these ideas are correct, Nelson's views on the nature of chronic murine pneumonia will need modification and, for long-term experiments of any kind with rats, it will be advisable to devise a more

natural diet which produces less dust than the conventional cubes.

We thank Mrs J. Morgan for preparing the Ouchterlony plates, and Mr Buist, of Allied Feed Mills Pty., Limited, for ingredients for the tests.

### Variation of Saccharoid Fraction in Diabetes Mellitus

In diabetes mellitus it is not only the concentration of blood sugar which is altered but also the "saccharoid fraction"—the difference between the total reducing capacity of blood and the true concentration of glucose<sup>1</sup>. The exact nature of the saccharoid fraction is not known, but it would seem to be a non-specific mixture of all the reducing substances present in the blood, including glutathione, creatinine, glucuronic acid and cysteine. The significance of this fraction of the blood in pathological conditions is not well understood.

In blood, a large amount of carbohydrate is also present in the form of mucopolysaccharides. When measured as hexosamine after acid hydrolysis, it is found to be present at about the same concentration as glucose in the blood. The effect of insulin on the disappearance of hexosamines from blood has also been investigated. Gaulden *et al.*<sup>2</sup> have shown that when acetyl glucosamine is injected intravenously into normal subjects the true concentration of glucose in the blood virtually remains unaffected. Weilden and Wood<sup>3</sup> have found that there is no difference between the disappearance of glucosamine from the blood of normal subjects and that from the blood of patients with diabetes. Spiro has compared the biosynthesis of glucosamine with that of liver glycogen in intact alloxan diabetic rats<sup>4</sup> and concludes that there is no impairment in the rate of synthesis of glucosamine despite an almost complete failure in the synthesis of glycogen.

The purpose of the present investigation was to observe the variation of saccharoid and mucopolysaccharide fractions of blood in normal and clinically diagnosed diabetic subjects during sugar tolerance test.

Glucose tolerance test was performed on human subjects who were divided into two groups according to whether they were diabetic or "normal". Ten normal control subjects with no evidence of diabetes mellitus were selected from among the male staff and students of Jinnah Postgraduate Medical Centre aged between 25 and 40 years. The other group consisted of twenty subjects diagnosed diabetics, only three of which were less than 40 years. The youngest member of this group was 14 years old and the oldest was 60. Sixteen of the group were males and four females. Ten patients were classified as moderately diabetic, six as acute and the rest mildly diabetic. The duration of the disease in these

Fig. 1. Concentration of total reducing sugar (A), true glucose (B) and hexosamine (C) during the sugar tolerance tests in normal subjects. Each value is the mean of ten subjects.

Fig. 2. Concentration of total reducing sugar (A), true glucose (B) and hexosamine (C) during the sugar tolerance tests in diabetic subjects. Each value is the mean of twenty diabetic subjects.

Fig. 3. The variation of the saccharoid fraction during sugar tolerance tests in normal (●—●) and diabetic (○---○) subjects. Each value is the mean of ten normal and twenty diabetic subjects. The vertical bars indicate  $\pm$  S.E.M.

cases varied between 6 months to 14 years. Nine patients had suffered for less than 2 years, seven for 2–6 years and the rest had been diabetic for more than 6 years. At least 48 h before collection of blood samples all antidiabetic drugs were discontinued and the subjects were fasted for at least 12 h before the sugar tolerance test was carried out.

After a sample of fasting blood had been withdrawn from the subjects they were given 50 g of D-glucose in solution to drink. Blood samples were collected in citrated tubes 1, 2 and 3 h later. The concentrations of total reducing sugar, true glucose and hexosamine were estimated for all blood samples. Sugar was determined in whole blood samples while hexosamine was estimated in the plasma. The total reducing sugar was estimated by the Folin-Wu method and the true glucose by the glucose oxidase and peroxidase ("Glucostat") method. Bound hexosamine was estimated by the method of Cessi and Piliego<sup>5</sup> after hydrolysis with 3 normal hydrochloric acid at 106° C overnight. The saccharoid fraction was expressed as mg per cent of the difference of the total reducing sugar and true glucose from individual values.

The results of the glucose tolerance tests are shown in Figs. 1 and 2. Fig. 1 shows the values obtained for normal subjects and it can be seen that the rise and fall

of the true glucose and total sugar in most of the subjects are not accompanied by a similar variation in the concentration of hexosamine. Fig. 2 shows similar values for the diabetic patients and here the variations in the true glucose and total sugar are more inconsistent than the values of hexosamine, which do not vary with the rise and fall of the sugar. The hexosamine content of the plasma, however, remained unchanged during glucose tolerance tests in both normal and diabetic patients.

The variation in the saccharoid fraction during glucose tolerance test is shown in Fig. 3. The increase and decrease in the values of the saccharoid fraction are similar to those for sugar. As the blood sugar rises the saccharoid fraction rises to a similar extent and this is so whether the subjects are normal or diabetic. In diabetes the concentrations of sugar in the blood varies considerably (Fig. 2), but the saccharoid fraction does not change significantly from the normal. As has already been pointed out, the saccharoid fraction represents a variety of non-glucose reducing substances present chiefly in the red cells<sup>6</sup>. The saccharoid fraction of normal human blood can be accounted for almost entirely by glutathione and glucuronic acid<sup>7,8</sup>. The reducing substances in the blood of diabetic subjects are the same as those in normal subjects and the increase in blood sugar is not related to an increase in them. The variation of the saccharoid fraction in the present investigations may result therefore from the conversion of the blood sugar to some fragment or phosphate esters of glucose which are reducing in nature and form a part of the saccharoid fraction which rises and falls with the concentration of sugar in the blood. Hexosamines, however, do not seem to contribute to this fraction.

It seems likely from these investigations that the saccharoid fraction and the circulating mucopolysaccharides are independent of the action of insulin because their behaviour in diabetic subjects is similar to that in normal subjects.

### Report of a New Site-specific Cleft Palate Teratogen

MORE than ten chemical teratogens are now known to produce cleft palate in various species of Rodentia. All these, however, show their teratogenic potential by a widespread embryopathy of which cleft palate is but one facet of a generalized teratogenic response; little or no site-specificity of action or anatomical localization occurs.

For example, Trasler<sup>1</sup> produced a widespread embryopathy in mice, using acetylsalicylic acid; lesions included cleft palate, short snout, microcephaly, polydactyly and exencephaly. Larsson *et al.*<sup>2</sup> used sodium salicylate to produce cleft palate and other widespread teratogenic effects in mice. In 1963, King<sup>3</sup> used meclozine hydrochloride in Sprague-Dawley rats to produce cleft palate, brachygnathia, microstomia and micromelia, and in 1958 Nishimura and Nakai<sup>4</sup> similarly produced a heterogeneous embryopathy, including cleft palate, using high dosage nicotine.

Fraser and Fainstat<sup>5</sup> used cortisone acetate in genetically susceptible mice to produce cleft palate. Although cleft palate was the predominant lesion, other teratogenic embryopathic features included shortening of the head, mandibular attenuation and spina bifida.

Similar widespread embryopathies which incorporate cleft palate in the teratogenic syndrome have been produced by trypan blue<sup>6</sup>, nitrogen mustard<sup>7</sup> and hyper-vitaminosis A (ref. 8).

It has been shown in this laboratory that a crude extract of *Indigofera spicata* is teratogenic in *Rattus norvegicus* (Sprague-Dawley strain) and that the embryopathy resulting from its oral administration is limited to cleft palate and somatic dwarfism. The discovery of a site-specific cleft palate teratogen in Rodentia is thus significant in that it enables the construction of an experimental model in which local morphopathogenic processes can be manipulated and studied.

*Indigofera spicata* is a palatable, hardy plant of high protein yield which possesses remarkable potential for pasture improvement in infertile tropical countries<sup>9</sup>. The plant is an efficient nitrogen-fixing legume. Its widespread use has been limited because of undesirable side effects, observed clinically in cattle and experimentally in rodents, which have included acute hepatotoxicity and abortion<sup>10-15</sup>. The exact chemical structure of the teratogenic moiety is not yet known. Because the suspected chemical structure of the toxic component of the extract does not correspond with that of the more common substances inducing abortion (ergot alkaloids, quinine, oxytocin, histamine) it was decided to subject the crude plant extract to teratogenic investigation.

Primiparous Sprague-Dawley rats of controlled lineage were used, and mated with stud bucks of the same strain. The spontaneous incidence of cleft palate in this rat colony is less than one in one thousand. No cleft palate occurred in control fetuses. The crude extract from the plant was administered orally at varying stages of gestation, and the fetuses examined following hysterectomy on the twenty-first day.

The embryopathic syndrome produced was limited to somatic dwarfism and cleft palate. No other physical defects were observed in autopsies of more than two hundred exposed embryos, of which 60 per cent had cleft palate. Details of dosage rate and time specificity will be presented in detail when a larger series of investigations has been completed and dose-response relationships calculated.

The cleft palate produced in this way is of the post-alveolar type involving only the secondary palate. Both hard and soft palates are involved.

If gestation is allowed to proceed to term, the fetuses with cleft palates induced by *Indigofera* extract are spontaneously delivered at the usual time; although born alive they do not live for more than a few hours. This is conceivably due to a defect in suckling with inhalation of milk into the lungs, but could also be related to a separate metabolic toxic effect of the teratogenic extract.

Very few chemical teratogens act with sufficient site-specificity to allow chemical and more sophisticated methods of investigation on a localized anatomical area. Thalidomide is probably an exception and its predilection for the left, first metacarpal bone in rabbits exposed to this drug is very striking<sup>16</sup>. In a similar fashion to cleft palate induced by *Indigofera* extract this site-specificity allows one to analyse meaningfully its morphopathogenic action.

Although the *Indigofera* extract produces isolated cleft palate as its only site-specific manifestation, some physical manipulations of the embryonic environment will produce an identical result. For example, puncture of the amniotic sac followed by surgically induced loss of amniotic fluid has been shown to cause this lesion as an isolated defect<sup>17,18</sup>.

Other physical manipulations of the embryonic environment will produce multiple non-specific defects among

which cleft palate is common. Intermittent clamping of the uterine artery and maternal hypobaric hypoxia will produce this state<sup>19,20</sup>. Irradiation of the pregnant uterus produces a similar effect<sup>21</sup>, in which cleft palate is but one abnormality in an embryopathic syndrome comprising more than one hundred features. It seems unlikely that comparative teratological studies using these less specific but intensively investigated research tools will be initially helpful in morphogenetic analysis of cleft palate induced by *Indigofera* extract.

The normal foetal palate closes after the primitive vertically disposed palatine shelves have turned horizontally and grown towards the midline<sup>22</sup>. Several workers have shown that the presence of the tongue interposed between these two shelves can prevent the fusion in certain pathological conditions<sup>23,24</sup>. It is uncertain whether the primary action of *Indigofera spicata* extract is mediated through the physical presence of the interposed tongue. Because of the localized nature of the malformation, however, the interposition of the tongue with failure of shelf apposition and fusion appears to be the most likely hypothesis to explain the observed findings.

The toxic extract was generously supplied by Dr M. P. Hegarty, Cunningham Laboratory, Commonwealth Scientific and Industrial Research Organization, Brisbane.

### Concentrations of Pyruvate, Pyruvate Kinase and Lactate Dehydrogenase in the Kidney of the Alloxan-diabetic Rat

INCREASED excretion of pyruvate has been observed in the urine of diabetic humans<sup>1</sup> and rats<sup>2</sup> which could not be correlated with blood pyruvate concentrations. This suggested that the increased excretion of pyruvate in diabetes was caused by altered kidney metabolism which in some way reduced the reabsorption of pyruvate in the kidney tubule. To investigate this possibility the concentrations of pyruvate and the activities of pyruvate kinase and lactate dehydrogenase are here reported in the kidney of the alloxan-diabetic rat and compared with the liver in the same condition.

Diabetes was induced in female Wistar rats, weighing 140–160 g, by an intravenous injection of alloxan monohydrate at a dose of 60 mg/kg of body weight. Diabetic rats had a concentration of blood glucose greater than 300 mg/100 ml. Normal rats of the same age and sex as the diabetic rats were allowed water and food (MRC diet 41B) freely and were killed by cervical dislocation and exsanguination 1–3 weeks after the induction of diabetes. Tissue pyruvate was estimated by a modification of the method of Hohorst *et al.*<sup>3</sup>. Tissues (0.5–1.0 g) were rapidly excised, frozen with tongs precooled in liquid nitrogen, and then pulverized and extracted into 4 ml. of 7 per cent (v/v) perchloric acid. After neutralizing with 5 molar potassium carbonate, estimations were carried out in 3.05 ml. containing 97  $\mu$ mole of  $\text{KH}_2\text{PO}_4$ - $\text{Na}_2\text{HPO}_4$  (pH 7.6), 1.5  $\mu$ mole of EDTA, 0.7  $\mu$ mole of NADH and 1.5 ml. of extract. The decrease in optical density at 340 m $\mu$  was measured 2 min after the addition of 25  $\mu$ g of lactate dehydrogenase. Blood was obtained by cardiac puncture from rats under ether anaesthesia and was used for the estimation of blood pyruvate by an adaptation of the method of Marks<sup>4</sup>. Enzymes were assayed in supernatants obtained by homogenizing tissues in four volumes of 0.154 molar potassium chloride at 4° C with a Potter-Elvehjem type homogenizer and centrifuging at 25,000g and 0° C for 2 h. Pyruvate kinase was assayed by the method of Bücher and Pfeleiderer<sup>5</sup> in 3 ml. of a mixture containing 100  $\mu$ mole of  $\text{KH}_2\text{PO}_4$ - $\text{K}_2\text{HPO}_4$  (pH 7.4), 300  $\mu$ mole of potassium chloride, 25  $\mu$ mole of magnesium sulphate, 25  $\mu$ mole potassium phosphoenolpyruvate, 6  $\mu$ mole of ADP, 2  $\mu$ mole of NADH and 0.1 mg of lactate dehydrogenase. Lactate dehydrogenase was assayed according to the method of Kornberg<sup>6</sup> in 3 ml. of a mixture containing 100  $\mu$ mole of  $\text{KH}_2\text{PO}_4$ - $\text{K}_2\text{HPO}_4$  (pH 7.5), 2  $\mu$ mole of sodium pyruvate and 0.4  $\mu$ mole of NADH. Assays were carried out at room temperature during a 5 min reaction period. Protein was estimated in the supernatant by a Folin-Ciocalteu<sup>7</sup> or biuret method, using a bovine plasma albumin standard.

Table 1. CONCENTRATIONS OF PYRUVATE IN KIDNEY, LIVER AND BLOOD AND OF PYRUVATE KINASE AND LACTATE DEHYDROGENASE IN THE KIDNEY AND LIVER OF ALLOXAN-DIABETIC AND NORMAL RATS

	Pyruvate ( $\mu$ mole/g wet weight)	Pyruvate kinase ( $\mu$ mole NADH oxidized/min/mg of protein in crude supernatant)	Lactate dehydrogenase ( $\mu$ mole NADH oxidized/min/mg of protein in crude supernatant)
Kidney			
Normal	43 $\pm$ 10* (14)†	145 $\pm$ 41 (22)	1,570 $\pm$ 390 (22)

Liver			
Normal	73 $\pm$ 33 (8)	345 $\pm$ 114 (11)	2,380 $\pm$ 550 (12)
Diabetic	34 $\pm$ 13 (7)	181 $\pm$ 53 (10)	2,820 $\pm$ 770 (11)
Blood	( $\mu$ mole/ml. of blood)		
Normal	210 $\pm$ 23 (7)		
Diabetic	244 $\pm$ 15 (7)		

\* Mean  $\pm$  1 standard deviation.

† Number of observations is in parentheses.

The results summarized in Table 1 show that in the kidney diabetes caused a 50 per cent increase in the concentration of pyruvate ( $P=0.001$ ), a 22 per cent increase in the activity of pyruvate kinase ( $P<0.05$ ) and a 20 per cent increase in the activity of lactate dehydrogenase ( $P<0.05$ ). In the liver, however, diabetes caused a 53 per cent decrease in the concentration of pyruvate ( $P<0.02$ ), a 53 per cent decrease in the activity of pyruvate kinase ( $P<0.001$ ) and no significant change in the lactate dehydrogenase ( $P<0.1$ ). Concentrations of blood pyruvate were 16 per cent higher in diabetic animals, but this elevation was not significant ( $P<0.3$ ).

With the exception of lactate dehydrogenase, the changes produced in the kidney by diabetes were opposite to those produced in the liver. The present observations in the liver of the diabetic rat agree with those of other authors with regard to pyruvate concentration<sup>8,9</sup> and the activity of pyruvate kinase<sup>10</sup> and lactate dehydrogenase<sup>11</sup>. It seems that the activity of pyruvate kinase in the kidney, unlike that in the liver, is relatively unaffected by alloxan-diabetes and changes in dietary regime<sup>12</sup>.

This is surprising because both kidney and liver possess a similar pyruvate kinase isoenzyme pattern<sup>12</sup> and therefore presumably similar properties. Furthermore, pyruvate kinase is a rate determining enzyme for glycolysis and is involved in the regulation of gluconeogenesis<sup>13</sup>. The results therefore suggest that not all the metabolic changes induced in the kidney by diabetes are necessarily identical to those induced in the liver. The results are also in accord with the recent suggestion<sup>14</sup> that insulin has only an indirect effect on the activity of pyruvate kinase. Lactate dehydrogenase, unlike pyruvate kinase, is a bidirectional non-rate-determining enzyme, and so its control is presumably not of crucial importance to the cell. Finally, the increased concentration of pyruvate in the diabetic kidney, a probable result of altered kidney metabolism, may in part explain the elevated excretion of urinary pyruvate in diabetes<sup>1,2</sup>.

## MICROBIOLOGY

### Antigenic Relationship between Influenza A Viruses of Human and Avian Origins

INFLUENZA A viruses causing natural infections in man, swine, horses and birds are indistinguishable from one another in the antigenic structure of their internal ribonucleoprotein (S or G antigen) but little or no relationship has been found between the human and animal strains which have been compared so far with respect to antigens present in the viral envelope (V antigens). This is not invariably the case, however, and V antigens common to certain strains of avian and mammalian origins have been observed (ref. 1 and B. Tumova and H. G. Pereira, to be published).

In the course of a comparative study of influenza A viruses isolated from man, pigs, horses and birds, a reciprocal cross reaction between human A2 viruses and a strain of avian origin (A/turkey/Massachusetts/3740/65) was detected in haemagglutination-inhibition (HAI) tests performed with sera from hyperimmunized rats. These cross reactions, although not considerable, were sufficiently striking to prompt us to compare the two strains in question in greater detail.

Initially, a total of fifteen distinct avian influenza A viruses, including all those previously described by Pereira *et al.*<sup>2,3</sup> and a number of additional strains investigated since then, were cross-tested with five human strains

including sub-types A0 (WS, PR8), A1 (FM1) and A2 (A2/Singapore/1/57, A2/Czechoslovakia/9/65) by HAI using hyperimmune rat sera. The only cross reactions observed were between A/turkey/Massachusetts/3740/65 and the two human A2 strains. HAI tests performed with sera from a ferret infected by A2/Singapore/1/57 by intranasal inoculation and from a chicken similarly infected with A/turkey/Massachusetts/3740/65 failed to reveal these cross reactions (Table 1).

Table 1. HAEMAGGLUTINATION-INHIBITION TEST

Strain	Antisera			
	A2/Singapore/1/57 Hyper-immune (rat)	Post infection (ferret)	A/turkey/Mass./3740/65 Hyper-immune (rat)	Post infection (chicken)
A2/Singapore/1/57	1,024	3,840	16	< 10
A2/Czech./9/65	128	NT	32	NT
A/turkey/Mass./65	32	< 10	256	160

Figures represent reciprocals of serum dilutions showing 50 per cent inhibition of 4 haemagglutinating doses of virus.

NT = not tested.

Table 2. STRAIN-SPECIFIC COMPLEMENT FIXATION TEST

Strain	Sera				
	A/turkey/ Mass./ 3740/65	A2/ Singapore/ 1/57	A2/Nether- lands/ 65/63	A2/ England/ 12/64	A2/Lenin- grad/ 29/65
A/turkey/Mass./ 3740/65	640	480	< 10	< 10	< 10
A2/Singapore/1/57	160	> 1,280	60	10	< 10
A2/Netherlands/ 65/63	< 10	240	960	240	320
A2/England/12/64	15	40	480	480	320
A2/Leningrad/29/65	< 10	10	320	80	640

Figures represent reciprocals of serum dilutions showing 50 per cent complement fixation against optimum antigen dilutions.

A number of human A2 strains were then compared with the turkey/Massachusetts virus by strain-specific complement fixation<sup>4</sup> with the results shown in Table 2. A clear antigenic relationship between turkey/Massachusetts and A2/Singapore/1/57 is demonstrated in this test. It may be noted that the degree of cross reactivity between these two strains is greater than between A2/Singapore/1/57 and any of the other A2 strains included in this test. Furthermore, little or no antigenic relationship could be detected between A/turkey/Massachusetts and any of the more recent A2 strains. Similar results were obtained by virus neutralization using sera from hyperimmunized rats (Table 3).

Table 3. VIRUS NEUTRALIZATION TEST IN CULTURES OF *Cercopithecus aethiops* KIDNEY CELLS

Strains (100 TC <sub>50</sub> )	Antisera		
	A2/Singapore/ 1/57	A2/Czech./ 9/65	A/turkey/Mass./ 3740/65
A2/Singapore/1/57	480	< 10	120
A2/Czech./9/65	20	> 640	40
A/turkey/Mass./3740/65	160	80	> 640

The figures represent reciprocals of serum dilutions showing 50 per cent neutralization (expressed in terms of haemadsorption inhibition against 100 haemadsorption units).

The fact that the antigenic relationship between A/turkey/Massachusetts and A2/Singapore/1/57 is revealed so much more clearly by strain-specific complement fixation than by HAI suggests that an antigenic component other than the haemagglutinin may be shared by these two viruses. The possibility that viral neuraminidase might represent this shared component was investigated by testing the capacity of rabbit antisera to human (A0, A1 and A2), porcine (SW) and avian (Fowl Plague and turkey/England/63) strains to neutralize the enzyme activity of homologous and heterologous influenza A viruses. The only outstanding heterologous reaction observed in this series of tests was between an antiserum to A2/Ann Arbor/23/57 and the A/turkey/Massachusetts strain. The antigenic relationship between early strains of human influenza A2 and A/turkey/Massachusetts is seen therefore to be detectable by four different techniques.

So close is the antigenic relationship between these two strains that the possibility that the materials under test contain a mixture of viruses must be taken into account. The possibility that the A/turkey/Massachusetts strain is

contaminated by a human A2 strain was considered first. Attempts to purify the strain by a plaque technique were unsuccessful because this virus, unlike most other avian influenza A strains, fails to produce plaques in chick embryo fibroblasts. The original freeze-dried material received at the World Influenza Centre was therefore titrated in eggs and limit dilution fluids obtained at two successive passages were found to behave in strain-specific complement fixation tests in exactly the same way as the material used for the tests shown in Table 2. Another possible explanation for the cross reactions observed is that the A/turkey/Massachusetts strain might have acquired an A2 antigenic component through genetic recombination resulting from a temporary contamination with an A2 strain. This seems unlikely because the isolation of this virus was performed in a laboratory where no human influenza viruses were being handled at the time. The material received at this centre had been through three allantoic passages before shipment and was tested after a single additional passage carried out under strict precautions against contamination. Finally, it should be mentioned in this connexion that strain A/turkey/Massachusetts, unlike A2/Singapore/1/57, cross reacts by HAI and strain-specific complement fixation with other avian influenza A viruses<sup>3</sup>.

These findings pose a number of interesting questions regarding the possible relationships between human and animal influenza viruses. If the A/turkey/Massachusetts strain had been isolated before 1957 it would have been tempting to suggest at that time that the human influenza A2 sub-type had been of avian origin.

### Buoyant Density of African Horsesickness Virus

It has been shown that in apparently pure strains of some animal viruses the buoyant density of the infective particles may differ<sup>1</sup>. A range of densities is usually demonstrated with two infectivity peaks which indicate a density difference of about 0.02 g/ml. This heterogeneity is explained by assuming that a varying amount of host lipid or other material is adventitiously incorporated in the virion during the assembly process.

A study of the A501 vaccine strain of African horsesickness virus has revealed a similar situation<sup>2</sup>. After more than two hundred intracerebral passages in suckling mice this virus was shown by caesium chloride density gradient centrifugation to have a density range of 1.05–1.375 g/ml., with infectivity maxima at 1.17 and 1.35 g/ml. (Fig. 1). The sedimentation coefficient of virus obtained from the two principal fractions was determined by method A of Polson and van Regenmortel<sup>3</sup>. It was found that the denser particles had a sedimentation rate of  $S_{20}^{w,0} = 240$  and a calculated particle diameter of 34.6 m $\mu$ ;

Fig. 1. Buoyant density of African horsesickness virus (Strain A501). The virus is untreated and shows infectivity maxima at 1.17 and 1.35 g/ml.

Fig. 2. Buoyant density of African horsesickness virus (Strain A501) after treatment with ether. Infectivity maxima at 1.08 and 1.32 g/ml.

the less dense particles had a rate of  $S_{20}^{w,0} = 561$  and a diameter of 74.9 m $\mu$ . With this virus, heterogeneity with respect to both size and density is apparent.

In order to test for the presence of contaminating loosely bound lipid on the surface of the virus particles, a sample of virus was shaken in 20 per cent, by volume, diethyl ether before caesium chloride density-gradient analysis. No change in the typical heterogeneous nature of the virus density occurred although the density of the two principal fractions was slightly reduced (Fig. 2). Most striking is the increase in the number of particles of high density apparently formed at the expense of those of lower density. There is little reduction in the total number of infectious particles and the change in the density distribution may therefore be ascribed to the removal of lipid material from the low density particles, thus increasing their density. Because the virus was obtained from brain material, which contains many lipid complexes, low density contaminants would not be unexpected.

A second experiment, designed to free the virus from possible contaminating material, was performed by subjecting a sample of the virus to ultrasonic irradiation. The virus was suspended in 0.06 molar phosphate buffer containing 5 per cent by volume rabbit serum (final pH 7.5) and was sonicated with a 60 watt MSE-Mullard disintegrator at 20 Kc/s for 30 min at 0°C. It may be seen from Fig. 3A that this treatment results in an increase in the number of infective particles of density 1.27 g/ml. with a considerable reduction in the number of viruses at both the higher and lower density positions. The virus concentrated at a position where very little infective material was present when untreated virus was used. Prolonged ultrasonic action for 45 and 60 min (Fig. 3B and C) resulted in a progressive change in the density pattern which altered to form a single major peak at a limiting buoyant density of approximately 1.23 g/ml.

The increase in density of the low density particles may be explained by suggesting that lipid material is removed from the virus by ultrasonic treatment resulting in the formation of denser infectious particles. With regard to the virus of higher density the loss of any material, other than nucleic acid, would also result in an

Fig. 3. Buoyant density of African horsesickness virus (Strain A501) showing effect of sonication. A, 30 min sonication. Infectivity maxima 1.15 and 1.275 g/ml.; B, 45 min sonication. Infectivity maxima 1.125 and 1.24 g/ml.; C, 60 min sonication. Infectivity maximum 1.233 g/ml. The arrow in C marks the position of dense opalescent matter in the gradient tube. Adsorption of virus to this matter probably resulted in a false infectivity peak at this position.

increase of density. Ultrasonic treatment reduces the density of these particles but their infectivity remains unimpaired. Nucleic acid essential for infectivity could not therefore have been removed from the virus. To explain the reduction of density of these infectious particles of high density, it must be presumed that there is an addition of lipid material or water or that non-essential nucleic acid, present on the surface of the virus, is removed.

The density pattern of "normal" or untreated infectious particles of this horsesickness virus strain can be reproduced and it seems that this factor may be under some genetic control. There is also the possibility that virus density is not always an unalterable characteristic of the particle but may depend on the presence of contaminating material, the method of purification, storage, etc., and possible interaction of the virus with the material which forms the gradient. The problem of exactly what constitutes "contaminating material" may be difficult to resolve, especially if the substance is incorporated within the body of the virus but released by various treatments. The changeable or mutable property of this horsesickness virus strain may be found to apply to other viruses. If this is the case, and if viral density is to be used to characterize viruses, a standard reproducible measure will have to be found. As shown in Figs. 1 and 3, sonication results in a progressive change towards an apparently constant density. This indicates that it may be advisable, when necessary, to define a kind of intrinsic density for viruses analogous to viscosity and other physical measures.

### Altered Esterase Zymograms associated with Infection with Leukaemia Virus

THE study of leukaemia viruses was until recently greatly hampered by the lack of cell cultures capable of propagating such viruses, but several cultures have now been found which support the replication of murine leukaemia virus. One of these cultures (*JLS V6*) originated from a mixture of *BALB/c* mouse spleen and thymus cells. Exposure of this culture to a cell free extract of leukaemic spleen from mice infected with Rauscher leukaemia virus (RLV) has resulted in a chronically infected culture (*JLS V5*) which continually propagates Rauscher virus<sup>1</sup>. In our laboratory, gross cytopathic effects are seen in such infected cells<sup>2</sup>. The infected cultures (*JLS V5*) also show a marked increase in mucopolysaccharide and a concomitant loss of contact inhibition, which results in a transformed "criss-cross" growth pattern. Such infected transformed cells have an enhanced tumorigenicity when they are injected into newborn *BALB/c* mice. The resultant tumours are rich in mucopolysaccharide and are classified as myxofibrosarcomata<sup>3</sup>. Tests to detect the presence in the infected cultures of other murine viruses to which the observed alterations might be attributable have been negative<sup>3</sup>. Moreover, newborn mice from mothers immunized with formalized extracts of spleen infected with RLV are resistant to challenge with the transplantable myxofibrosarcoma cells, whereas newborn mice from mothers immunized with extracts of normal spleen tissue show no such resistance<sup>4</sup>. The uninfected control cells (*JLS V6*) do not show gross cytopathic effects or transformation and are much less tumorigenic. Furthermore, the tumours that do result from injection

Fig. 1. A, Uninfected *JLS V6* culture showing only slight staining with insoluble fast-blue-RR- $\alpha$ -naphthyl complex, indicative of slight esterase activity. B, *JLS V5* culture infected with the Rauscher leukaemia virus showing marked esterase activity, as judged by increased reactivity with the same stain.

Fig. 2. Esterase zymograms of control cell cultures and cell cultures infected with Rauscher virus, with corresponding densitometric recordings. A, Control cells, 15.1 mg protein extract, showing only one enzyme band and corresponding densitometric recording. B, Cells infected with Rauscher virus, 9.93 mg protein extract, showing seven resolvable bands of esterase activity and their corresponding densitometric recording. Values shown above each numbered peak are units of relative activity of each esterase band determined from the electronically integrated area under each respective peak. The integrated areas are delineated by the vertical lines in the densitometric recording. Activity is corrected to 1 mg of protein extract.

of non-infected control cells are classified as spindle-cell sarcomata<sup>3</sup>.

The metabolic alterations in *JLS V5* cells infected with the Rauscher virus, as indicated by stimulation of mucopolysaccharide formation and neoplastic transformation, prompted us to investigate the effect of the virus on protein and enzyme synthesis in such cells. The first class of enzymes studied was the non-specific esterases. For this purpose, infected *JLS V5* and control *JLS V6* cells were cultured on standard 75 × 35 mm glass slides in Eagle's basal medium with a four-fold concentration of amino-acids and vitamins and 10 per cent calf serum. Before the cell sheet became confluent (24–48 h after sub-culturing), non-specific esterase activity was determined histochemically with  $\alpha$ -naphthyl butyrate as substrate and fast blue RR salt as the diazo-coupling agent, after the method of Markert and Hunter<sup>5</sup>. The slides were washed and then examined microscopically for an insoluble fast blue RR  $\alpha$ -naphthyl complex which would indicate esterase activity. In addition, washed cell pellets of control (*JLS V6*) and infected (*JLS V5*) cultures were homogenized with tissue grinders; the cell free extracts were subjected to electrophoresis on acrylamide gel; and the esterase activity in the gel was determined with  $\alpha$ -naphthyl butyrate as the substrate<sup>6</sup>. The resultant esterase zymograms were quantified densitometrically, as previously described<sup>6,7</sup>. Tissue culture fluid overlying the control and infected cultures was tested in a similar way.

The infected *JLS V5* cells which had been histochemically stained for esterase activity showed a marked increase in staining intensity compared with the uninfected *JLS V6* cells (Fig. 1). The small rounded cells in the infected cultures showed a particularly high esterase activity. Because in cover-slip preparations the cells were not confluent when stained, the increased intensity of staining of the infected cultures should not merely be a reflexion of decreased contact inhibition. The marked increase in esterase activity of the infected cultures is also evident when the zymograms from infected and control cell extracts are compared (Fig. 2). In three separate experiments, the zymograms from the extracts of infected cells showed an increase in total esterase activity by a factor of between fifteen and thirty for each mg of protein, which was attributable to the appearance of at least six additional electrophoretically distinguishable esterases (Fig. 2). Little or no esterase activity was detected in the culture media from either control or infected cultures.

The significance of the alterations in esterase activity associated with RLV infection cannot at present be fully assessed. As previously noted, the infected cultures continuously propagate infectious virus. Titrations in mice of cell free tissue culture fluid from the infected cultures show titres in excess of  $10^3$  ID<sub>50</sub>/ml. of fluid (unpublished data). It is thus of particular interest to explore the part, if any, that the additional esterase bands play in the synthesis of infectious leukaemia virus and to determine whether these bands represent derepressed cellular esterases or "new" esterase coded for by the viral genome. Induced enzyme synthesis after infection with other oncogenic viruses, such as polyoma and SV<sub>40</sub>, is well documented<sup>8,9</sup>. Conversely, the infected cells are highly phagocytic<sup>10</sup> and the altered esterase activity may be related to the phagocytosis and resultant formation of lysosomes in these cells. Studies are also under way to determine whether the alterations in the mucopolysaccharide in *JLS V5* cells are related to the altered esterase patterns in these cells and to determine whether other tissues which propagate the RLV, either *in vitro* or *in vivo*, show similarly altered esterase patterns.

### Action of Sendai Virus and Neuraminidase on the Alkaline Phosphatase Isoenzymes of HeLa Cells

THE mechanism of virus induced cell fusion is not clear. Among others, Sendai virus<sup>1,2</sup> and Newcastle disease virus<sup>3</sup> have been used to induce cell fusion; both viruses belong to the myxovirus group. In the early stages of fusion the virus is absorbed onto the cell surface and cytoplasmic bridges are formed between adjacent cells<sup>4</sup>. Okada<sup>5</sup> has measured the haemolytic, haemagglutination and sialidase activities of Sendai virus, but found that the ability of the virus to fuse cells together could not be correlated with these activities. Kohn<sup>6,7</sup> has investigated the effect of modified Newcastle disease virus on animal cells and found that fusion was prevented only when the lipid membrane of the virus was hydrolysed. Kohn<sup>6</sup> also found that treatment of the cells with neuraminidase

before the addition of virus also prevented fusion. The presence of sialic acid residues in the cell wall has been described by Kraemer<sup>8</sup> and these residues could be the site of action of neuraminidase. The myxoviruses have a lipoprotein surface with mucopolysaccharide "haemagglutination spikes"<sup>9</sup> and it is thought that the neuraminidase is situated between these spikes, as appears to be the case for influenza virus<sup>10</sup>.

Neuraminidase (*N*-acetyl neuraminidate glycohydrolase *E.C.* 3.2.1.18) has been shown to reduce the mobilities of alkaline phosphatase isoenzymes from human kidney to give a single band of low mobility<sup>11</sup>. This effect was considered to be due to the removal of different amounts of sialic acid bound to the various isoenzymes.

The work reported here compares the effect of neuraminidase and Sendai virus on HeLa cells and on a homogenate of these cells with respect to the alkaline phosphatase isoenzymes.

HeLa cells were obtained from stock cultures and before electrophoresis all samples were grown as monolayer cultures for at least 24 h. The cells were treated with Sendai virus as described by Harris *et al.*<sup>2</sup> using 10<sup>8</sup> HeLa cells and 2,000 HAU of Sendai virus inactivated by ultra-violet light. The action of neuraminidase on monolayer cultures was investigated by incubating a 24 h monolayer (about 2 × 10<sup>6</sup> cells) with 100 units of neuraminidase in 20 ml. of medium for 4 h at 37°C. Longer incubations with neuraminidase caused cell death. Samples were taken for electrophoresis after cultivation in a medium free from neuraminidase after a further 24 and 72 h. A similar experiment was carried out by incubating a HeLa monolayer with 2,000 HAU of Sendai virus for 30 min. The monolayers were trypsinized and the cells homogenized according to Morton's butanol procedure<sup>12</sup>.

To test the action of neuraminidase and Sendai virus on a homogenate of HeLa cells, 1 ml. of butanol extracted homogenate was incubated overnight at 37°C with 50 units of neuraminidase or 3,000 HAU of Sendai virus.

The alkaline phosphatase isoenzymes were separated by acrylamide gel disc electrophoresis according to Davis<sup>13</sup>. A 5 per cent gel was used and the potassium ferriyanide inhibitor was omitted from the gel. After electrophoresis the isoenzyme bands were located by staining the gels in a solution of 12 mg sodium β-naphthyl phosphate and 90 mg fast blue BB in 60 ml. 0.2 molar *tris*-hydrochloric acid buffer (pH 8.1). After 20 min the gels were washed and stored in 7 per cent acetic acid. pH 8.1 was used for staining the gels in order to reduce the background stain caused by decomposition of the diazo coupler.

The isoenzyme patterns obtained are shown in Fig. 1. Gel *a* shows the normal distribution obtained from a monolayer culture. The fastest band is weaker than the others and the slowest band is diffuse and slightly variable in its position.

The patterns for the cells 24 and 72 h after treatment with virus are shown in gels *b* and *c*. They show an almost complete loss of the three fast definite bands and a spread of the slow diffuse band. When the monolayer culture was treated with neuraminidase a similar pattern was obtained (*d* and *e*). In this case cell fusion had not occurred to any appreciable extent as judged from monolayers on coverslips which had been similarly treated and stained<sup>2</sup>. The electrophoretic pattern obtained from the monolayer treated with virus again showed the loss of the discrete bands and an accumulation of the slow diffuse band (*f* and *g*). Coverslip cultures of cells treated with Sendai virus showed that there had been some cell fusion, but the yield of fused cells was much less than that produced by the procedure of Harris *et al.*<sup>2</sup>.

Gels *h* and *i* show the action of neuraminidase and virus on a butanol extracted homogenate of HeLa cells. Neuraminidase has had the same effect on the electrophoretic pattern as before but the virus has caused a negligible alteration.

Fig. 1. Alkaline phosphatase isoenzyme patterns on acrylamide gel electrophoresis of: HeLa monolayer control (*a*); HeLa cells treated with virus<sup>2</sup> after a further 24 h (*b*) and 72 h (*c*); HeLa monolayer treated with neuraminidase for 4 h, cultured for a further 24 h (*d*) and 72 h (*e*); monolayer treated with virus for 30 min, cultured for a further 24 h (*f*) and 72 h (*g*); homogenate incubated overnight with neuraminidase (*h*) and homogenate incubated overnight with virus (*i*).

These experiments show that neuraminidase can reduce the mobilities of the fast isoenzyme bands, with an apparent increase in the amount of the slow moving material. The simplest explanation is that of Butterworth and Moss<sup>11</sup> which suggests that the isoenzymes have sialic acid bound to them to various extents and that the sialic acid can be removed by incubation with neuraminidase. The resulting proteins then migrate on electrophoresis with similar mobilities. The presence of sialic acid is not necessary for enzyme activity because the treated material stained as well as the controls. From the poor resolution of the slow band it is not possible to decide whether the only difference between the isoenzymes lies in the amount of bound sialic acid or whether there are also other differences which are not resolved on electrophoresis.

When HeLa cells are incubated with Sendai virus then the change in isoenzyme distribution is identical with that found for neuraminidase-treated cells (*b*, *c*, *f* and *g*). It is probable that this action of the virus results from the presence of neuraminidase in the virus<sup>5,6</sup>. It appears, however, that, before the neuraminidase activity can become effective, it is necessary to alter the structure of the virus particle; when virus is incubated with a cell homogenate no change in the isoenzyme distribution occurs (*i*). The release of viral components when the virus is absorbed on to a cell surface appears to be a rapid process<sup>14</sup>. The presence of alkaline phosphatase in the cell membrane has been described by Lansing *et al.*<sup>15</sup> and this could form part of the receptor sites which are required for viral absorption<sup>6</sup>.

## PHYSIOLOGY

## Changes in Haemolymph Lipoproteins during Locust Flight

MUCH of the energy for long distance flight in locusts is derived by oxidation of lipids<sup>1</sup>, and the lipid is transported from the fat body (the principal site of lipid storage) to flight muscle through the haemolymph. During flight the lipid content of the haemolymph of *Locusta migratoria* increases to four times the resting value<sup>2</sup> and this is accounted for by an increase in the glyceride fraction. Chino and Gilbert<sup>3</sup> found that diglyceride is released from fat body during *in vitro* incubations with haemolymph, and suggested that diglyceride is important in lipid transport in the several insect species they studied. In mammals lipids are transported chiefly in the form of lipoproteins, and this is also so in a number of insect species<sup>3-5</sup>. We have therefore examined the nature of the increase in glyceride which occurs during locust flight, and have attempted to relate this to changes in haemolymph lipoproteins.

Adult male *Schistocerca gregaria* were used 14-18 days after the final moult, and samples of haemolymph were obtained from the cervical region by puncture with a glass capillary. Electrophoresis of haemolymph was carried out on cellulose acetate strips using 0.05 molar sodium glycinate buffer, pH 9.8; proteins were detected by staining with nigrosine and lipids were detected on separate strips by oxidation with hydrogen peroxide followed by staining with Schiff reagent. Lipids were estimated by direct densitometry of the stained strips.

Electrophoresis of haemolymph from resting locusts showed eight protein components (Fig. 1), only two of which (group A) usually contained lipid. When insects were flown<sup>1</sup> for 2 h the total lipid content of the haemolymph increased to between three and four times the resting value (as estimated by densitometry of electrophoretograms). Part of this increase was accounted for by an increase in the lipid content of the group A lipoproteins to 2.5 times the resting value. In addition lipid appeared in a second pair of proteins (group B, Fig. 1). After a flight lasting 2 h, 70 per cent of the total haemolymph lipid was associated with group A lipoproteins and 30 per cent with group B lipoproteins. Three hours after flight had stopped the haemolymph lipoprotein pattern had returned to the resting state.

Fig. 1. Electrophoresis of locust haemolymph proteins. (Cellulose acetate; pH 9.8.)

These results were confirmed by the results of other experiments in which locusts were fed from the time of the final moult on a diet containing [ $U-^{14}C$ ] palmitate. The fat bodies of such insects was found to be labelled principally in the lipid fraction; less than 1 per cent of the radioactivity was present as carbohydrate. Electrophoresis of haemolymph from resting animals showed that almost all the radioactivity was present in the group A lipoproteins. After a flight of 2 h the radioactivity of group A lipoproteins had increased, and an additional radioactive area was present coincident with group B lipoproteins. More than 95 per cent of the total radioactivity of the haemolymph was accounted for in these two fractions.

The radioactive lipids were further examined by extraction of haemolymph with chloroform/methanol<sup>6</sup> followed by thin-layer chromatography<sup>7</sup> of the extract.

Table 1. DISTRIBUTION OF RADIOACTIVITY IN HAEMOLYMPH LIPIDS BEFORE AND AFTER FLIGHT

	C.p.m. in 0.01 ml. haemolymph	
	Before flight	After flight
Total haemolymph radioactivity	180	680
Fatty acids	5	6
Diglycerides	26	540
Triglycerides	140	110

Table 1 shows that the main increase in lipid radioactivity after a flight of 2 h was accounted for by an increase in the diglyceride fraction; the triglyceride and free fatty acid fractions remained fairly constant.

The lipids of lipoproteins which had been electrophoretically separated from haemolymph from flown insects were examined by thin-layer chromatography. Group A lipoproteins contained both triglyceride and diglyceride, whereas group B lipoproteins contained chiefly diglyceride.

These results show that the extra demand for lipid substrates during locust flight is reflected by an increased concentration of lipid bound to protein in the haemolymph, and that one group of proteins (group B) carries lipid only when the concentration of lipid is high. Haemolymph from resting locusts at different stages of development has been examined qualitatively. Lipid in the group B fraction was present at two stages: fifth instar hoppers just before moulting and female adults during egg production. At both these stages demand for fat body lipid is likely to be high so the presence of lipid in the group B fraction seems to be related to extensive lipid mobilization from the fat body.

High concentrations of fuels in insect haemolymph are an adaptation to the rapid rates of fuel utilization of active flight muscle<sup>8</sup>. The considerable increase in haemolymph diglyceride during flight may be a response to an increased requirement by flight muscle for lipid in this form. It is noteworthy that flight muscle lipase of the *Cecropia* moth hydrolyses diglycerides at five times the rate of triglycerides<sup>9</sup>. Until the turnover rates of the haemolymph lipids during flight are known, however, it is difficult to assess the relative contributions of the different forms of lipid to flight metabolism.

We thank the Anti-Locust Research Centre for supplies of locusts.

### Autoradiography of Decamethonium in Rat Muscle

DECAMETHONIUM and other depolarizing drugs have a pharmacological effect at the endplate and adjacent regions of muscle fibres. Various modes of action have been proposed for these compounds; some are based on attachment to surface receptors while others require penetration into the fibres. In the work reported here the location of labelled decamethonium has been sought by means of autoradiograms prepared from frozen sections. With this method the distribution of the drug within the fibre can be determined and the movements of the water-soluble compound during processing can be prevented.

Decamethonium-( $^3\text{H}$ -methyl) dichloride was injected into rats which had been anaesthetized with sodium pentobarbitone (40 mg/kg). A dose of decamethonium was selected (1.64 mg/kg) which gave a minimal effect on contractions of gastrocnemius muscle which were obtained by stimulation of the sciatic nerve, and respiration continued without assistance. The muscles were removed after known times and plunged into iso-pentane cooled in liquid nitrogen. Frozen sections ( $5\mu$ ) were picked up on slides or coverslips which had been coated with sensitive emulsion, and after exposure at  $-20^\circ\text{C}$  for 3–10 days the silver grains were developed<sup>1</sup>, and the endplates were stained<sup>2</sup>.

Fig. 1 shows a transverse section of diaphragm muscle which was frozen 3 min after injection of labelled drug. Three endplates can be seen in the left section. The microphotographs were taken with dark-field illumination and incident lighting so that the silver grains reflect the light and appear as bright specks on a dark background<sup>3</sup>. The position of the grains indicates that the radioactive compound has penetrated into the fibres. The section on the right was obtained several mm away from the endplate region, and the muscle fibres at this point show few grains. The cluster of grains in the top right-hand corner corresponds to a group of blood vessels which contain radioactive material. Muscles removed 3–90 min after injection gave results which were similar to those shown in Fig. 1.

The distribution of grains along the fibres was studied in longitudinal sections of peroneus muscle. Light was reflected from the grains and collected in a photometer the readings of which were proportional to the grain density<sup>3,4</sup>. Fig. 2 shows measurements obtained from a single fibre. The radioactivity as indicated by the photometer readings was high in the region of the endplate and extended for several hundred microns on either side.

Fig. 1. Autoradiograms obtained from a diaphragm which was frozen 3 min after injection of labelled decamethonium. The transverse sections were photographed with dark-field illumination. The section on the left shows three stained endplates. The white dots show light reflected from the silver grains, and indicate radioactivity within the fibres. The section on the right was taken several mm away from the endplate region, and the fibres show few grains. A group of blood vessels in the top right-hand corner contain radioactive material.

Fig. 2. Photometric estimation of radioactivity in a muscle fibre. An autoradiogram was prepared from a longitudinal section of peroneus longus muscle which was removed 60 min after injection of decamethonium. The light reflected from the grains was recorded at various distances from the endplate. The blank value, obtained from a part of the slide having no grains, has been subtracted, and a Gauss curve has been fitted to the points.

Fig. 3. Autoradiograms of hemi-diaphragms which were removed 15 min after injection of labelled decamethonium. The tissue was arranged with the rib above and the central tendon below. On the left the dark band of silver grains indicates radioactivity in the region of the endplates. The autoradiogram on the right was from a rat which was pretreated with 7-tubocurarine (0.8 mg/kg); the band which corresponds to the position of the endplates (see arrows) is much fainter.

Fig. 4. The left side shows an autoradiogram of a diaphragm which was removed 2 h after injection of labelled drug. The orientation is as Fig. 3. The horizontal band indicates uptake in the region of the endplates. The autoradiogram on the right was obtained from a muscle removed 7 days after injection of the same dose of decamethonium. The width of the band is increased and the radioactivity has spread along the fibres.

A peak of radioactivity in the region of the endplate has also been found in diaphragm muscle which was dissolved and counted by liquid scintillation, and the uptake

of decamethonium can be largely prevented by previous treatment with *d*-tubocurarine<sup>6</sup>. This effect of the antagonist has been confirmed by preparing transverse sections, and also by a different method the results of which are shown in Fig. 3. These autoradiograms were obtained by placing intact hemi-diaphragms in contact with slides which had been coated with emulsion. At the end of the exposure the muscles were removed and the autoradiograms were developed and photographed. The left side of Fig. 3 shows a dark band of silver grains which correspond to the position of the endplates in the stained diaphragm<sup>6</sup>. The right side of Fig. 3 was obtained from a rat which had received *d*-tubocurarine chloride (0.8 mg/kg) 10 min before injection of decamethonium. The density of silver grains in the band at the endplate region was much reduced, and with a larger dose of antagonist the band could be abolished.

Diaphragm muscles which have taken up labelled decamethonium lose their radioactivity at a slow rate. Fig. 4 shows autoradiograms from muscles which were removed 2 h and also 7 days after injection. After 7 days the band of silver grains is considerably wider, and this appearance is consistent with slow diffusion of decamethonium along the fibres.

This research was supported by grants from the Medical Research Council. We thank Dr A. W. Rogers for the use of equipment which was used for Figs. 1 and 2.

### Diffusion of Decamethonium in the Rat

Creese and MacLagan have reported evidence that labelled decamethonium enters the fibres of striated muscles when the drug is injected into rats (preceding communication). It was found that this radioactivity is lost slowly from the muscles and can still be detected after days or weeks.

The upper histogram in Fig. 1 shows the distribution of radioactivity in a diaphragm which was removed 2 h after injection of decamethonium-<sup>3</sup>H-methyl) dichloride into the tail vein of a rat. The dose (1.64 mg/kg) produced a transient weakness in some animals and no obvious effect in others. The left diaphragm was removed, frozen, sectioned into strips 1 mm wide and the radioactivity was expressed as counts min<sup>-1</sup> mg<sup>-1</sup>. The counts showed a peak in the region of the endplate, as found<sup>1</sup> previously, and a Gauss curve could be fitted to the results.

The lower histogram in Fig. 1 was obtained from a rat which was injected with the same dose of decamethonium and kept for 10 days before the diaphragm was removed. Considerable radioactivity remained in these muscles and it appeared that less than half had been lost. The Gauss curve is more dispersed, and this would be expected if there had also been some degree of diffusion along the fibres<sup>2</sup>. This interpretation is supported by the spread of radioactivity among the muscle which was shown in autoradiograms (preceding communication).

Curves can be fitted to the histograms of the form

$$y = d + A \exp \left\{ -\frac{(x - \mu)^2}{2\sigma^2} \right\} \quad (1)$$

where  $y$  represents counts min<sup>-1</sup> mg<sup>-1</sup> and  $x$  is the distance in millimetres from the tendon. The Gauss curves were found by a method to be described separately in which the parameters  $d$ ,  $A$ ,  $\mu$  and  $\sigma$  were computed to give a fit with least squares. In twelve muscles removed after 2 h the mean standard deviation  $\sigma$ , was 0.802 mm (range 0.614–1.17), while for twelve muscles removed after 10 days  $\sigma$  was 1.64 mm (range 1.33–2.03). Intermediate values were obtained which were consistent with these results. The lower curve of Fig. 1 is still diminishing at the ends, and with longer times the effects of reflexion may become significant<sup>3</sup>.

Fig. 1. Upper histogram shows radioactivity of rat diaphragm which was removed 2 h after injection of labelled decamethonium. The muscle was cut into strips 1 mm wide, and a Gauss curve has been fitted to the counts. The lower histogram was obtained from a rat which was injected and kept for 10 days before removal of the diaphragm. The standard deviation  $\sigma$  of the lower curve is indicated.

For longitudinal diffusion

$$\sigma_2^2 - \sigma_1^2 = 2D't \quad (2)$$

where  $D'$  is the apparent diffusion coefficient and  $t$  is the time. Thus  $D'$  is  $1.2 \times 10^{-8}$  cm<sup>2</sup> sec<sup>-1</sup>. This rate is very slow, and differs from the unidirectional transport which has been demonstrated in nerve axons<sup>4</sup>. The diffusion coefficient of labelled decamethonium in the interspaces of isolated rat diaphragm was found to be  $2.4 \times 10^{-6}$  cm<sup>2</sup> sec<sup>-1</sup>—the method being similar to that used previously<sup>5</sup>. The figure for internal diffusion is 200 times smaller than that for the interspaces, which in turn is less than in free solution<sup>6</sup>.

Decamethonium enters the fibres of rat muscle in the region of the endplate, and then migrates towards the ends of the fibres and is slowly lost. These results apply to the labelled compound which remains after injection, and the early distribution of the drug has not been explored.

## Effect of Calcium Ions on the Release of Acetylcholine from the Cerebral Cortex

THE presence of calcium ions ( $\text{Ca}^{2+}$ ) in the external medium is essential for the release of acetylcholine (ACh) at peripheral synapses (superior cervical ganglion, neuromuscular junction)<sup>1-6</sup>. Evidence now suggests that ACh is a transmitter in the cerebral cortex, and several investigators have shown that this substance is continuously released from the cerebral cortex in amounts which can be directly related to the level of cortical activity<sup>7-12</sup>. This communication describes how changes in local  $\text{Ca}^{2+}$  affect the spontaneous and evoked release of ACh from the cat cerebral cortex.

*d*-tubocurarine chloride ( $10^{-5}$  g/ml., California Biochemical Corporation). This procedure abolished the response to standard solutions of ACh, as well as to the active principle present in the samples. The results were analysed statistically by using Student's *t* test.

When the normal Ringer-Locke solution was changed for one containing no calcium chloride, there was a significant fall (of 34 per cent on average) in the amount of ACh collected from the surface of the cerebral cortex in the absence of peripheral stimulation (Table 1). The depressant effect of the lack of  $\text{Ca}^{2+}$  was readily reversed by restoring  $\text{Ca}^{2+}$  to the collection fluid. It is interesting that the action of  $\text{Ca}^{2+}$  is exerted only on a portion of the spontaneous release of ACh, while the remaining fraction

Table 1. MEAN RATE OF ACETYLCHOLINE RELEASE (ng/min/cm<sup>2</sup>) FROM UNSTIMULATED CEREBRAL CORTEX INTO RINGER-LOCKE SOLUTION CONTAINING DIFFERENT CONCENTRATIONS OF  $\text{Ca}^{2+}$

Region	No. of cats	Rate in 2 mmolar	Rate in 1 mmolar	Rate in 0.2 mmolar	Rate in 0 mmolar	P
Sensory-motor and parietal cortex	12	0.74 ± 0.09 (S.E.)	—	—	0.49 ± 0.06	< 0.05
	2	0.90 ± 0.20	0.81 ± 0.19	—	—	*
Sensory-motor cortex	4	0.48 ± 0.12	—	0.36 ± 0.07	—	*

\* These data are of a preliminary nature, but they suggest that there is no effect of low- $\text{Ca}^{2+}$  solution (0.2 mmolar and 1.0 mmolar) on the rate of release of ACh as compared with the control values.

Experiments were performed on cats anaesthetized with a mixture of diallyl-barbituric acid and urethane ('Dial', Ciba, Ltd.) given intraperitoneally (0.7–0.8 ml/kg). ACh was collected from the exposed surface (1 cm<sup>2</sup>) of the pericruciate and suprasylvian cortex, using the 'Perspex' chamber technique described before<sup>7</sup>. The chambers were filled with 1 ml. of Ringer-Locke solution containing eserine sulphate ( $1 \times 10^{-4}$  g/ml., British Drug Houses) and aerated with 5 per cent carbon dioxide in oxygen. The Ringer-Locke solution used had the following ionic composition: 137.0 mmolar sodium chloride; 2.5 mmolar potassium chloride; 2.0 mmolar calcium chloride; 1.0 mmolar magnesium chloride; 1 mmolar sodium phosphate; 12.0 mmolar sodium bicarbonate; and 11.0 mmolar glucose.

was unaffected by the absence of calcium. This result is qualitatively in agreement with the data obtained at mammalian motor nerve terminals<sup>4-6</sup>.

Mitchell<sup>9</sup> has reported that electrical stimulation of a peripheral sensory nerve produced an increase in the rate at which ACh was liberated from the surface of the contralateral sensory cortex. Using this procedure we have found that with 0.2 mmolar  $\text{Ca}^{2+}$  and with  $\text{Ca}^{2+}$ -free solutions there is no increase in the output of ACh during peripheral stimulation (Table 2). These results are of interest, because in all synapses so far examined the release of the chemical transmitter by the nerve impulse requires the presence of  $\text{Ca}^{2+}$  in the external medium. It seems that the cerebral cortex is not an exception to this. These observations also provide supporting evidence for the

Table 2. MEAN RATE OF SPONTANEOUS AND EVOKED ACETYLCHOLINE RELEASE (ng/min/cm<sup>2</sup>) FROM CEREBRAL CORTEX INTO RINGER-LOCKE SOLUTION CONTAINING DIFFERENT CONCENTRATIONS OF  $\text{Ca}^{2+}$

Region	No. of cats	[ $\text{Ca}^{2+}$ ]	Resting rate	Rate on contralateral forepaw stimulation	P
Sensory-motor cortex	8	2 mmolar	0.54 ± 0.09 (S.E.)	0.81 ± 0.09	< 0.05
	8	0.2 ± 0 mmolar	0.39 ± 0.05	0.42 ± 0.05	Not significant

The concentration of  $\text{Ca}^{2+}$  was varied in different experiments ( $\text{Ca}^{2+}$ -free, 0.2, 1.0 and 2.0 mmolar) by omitting calcium chloride; the other ions and the concentration of eserine remained constant. The small changes in osmolarity were not corrected for. The stimulating pulses were usually rectangular pulses lasting 1 msec, delivered at a frequency of 0.5/sec to the contralateral forepaw, through a radio-frequency isolation unit of the Grass 'S8' stimulator. Efficiency of stimulation was checked by recording the evoked potential with a cathode-ray oscilloscope. ACh was sampled from the surface of the cerebral cortex unilaterally for between fifteen and eighteen collection periods, each of 15 min duration. The usual procedure was as follows: two resting samples alternated with a stimulated one, first with normal (2.0 mmolar  $\text{Ca}^{2+}$ ) Ringer-Locke and then the sequence was repeated with low- $\text{Ca}^{2+}$  or  $\text{Ca}^{2+}$ -free solution. In this way, we were able to detect a significant change in the release of ACh, which was reproducible. Immediately after removal, samples were frozen at  $-15^{\circ}\text{C}$  and stored at that temperature.

Bio-assays were performed within 48 h of collection on the dorsal muscle of the leech (*Hirudo medicinalis*). As a control, muscle was soaked for 10 min in a solution of

involvement of ACh as a synaptic transmitter in the cerebral cortex.

## Electrical and Mechanical Responses of the Skeletal Muscle of a Primitive Insect

INNERVATION of arthropod excitatory muscle is of two types, distinguished by mechanical effect; these are "fast" (twitch) and "slow" (tonic), and only in the fast type is there a significant mechanical response to a single nerve impulse. The classes Insecta and Crustacea are the only arthropods the neuromuscular mechanisms of which have been studied in any depth, and considerable differences have been found between them, both in the anatomy and in the form of electrical events which accompany the fast and slow mechanical responses. Nearly all insect muscle fibres are fast-innervated and the electrical response is large, with a non-propagated spike component (active membrane response). Some fibres are also slow-innervated, and in these the electrical response is much smaller, but summates and facilitates greatly to repetitive stimulation, producing large depolarizations<sup>1-5</sup>. In crustaceans there are relatively fewer fast-innervated fibres, but all are slow-innervated. The two types of response are often difficult to distinguish electrically, and the fast response has no spike component; summation is incomplete although facilitation can be significant, and large depolarizations to either fast or slow stimulation are very rare<sup>6,7</sup>. Investigations of some of the more primitive insects could possibly show some responses which do not have the large spike activity of the higher insects, and some interesting neuromuscular patterns have been discovered in dragonfly larvae (species of *Aeschna*) which are thought to be primitive for several other reasons.

Excised preparations of the extensor tibia muscle and of the coxal depressor of trochanter muscle (here referred to as the coxal muscle) of the mesothoracic leg of late-instar *Aeschna* nymphs were mounted on the wax bed of a 'Perspex' chamber. They were covered with a saline of the following composition in mmoles/l.: 136 of sodium ions, 6 of magnesium ions, 10 of calcium ions, 156 of chloride ions, 16 of bicarbonate ions and 160 of sucrose. The distal apodeme was attached to the plate of an RCA '5734' mechano-electric transducer valve, and the innervating nerve trunk, which was left attached to the excised ganglion, was stimulated by a suction electrode. Electrical responses of the muscle fibres were recorded intracellularly.

The coxal muscle is innervated by a single excitatory nerve fibre, which is of the slow type. This block is thus unique among known insects, although muscles are known in which a few fibres are only slow-innervated<sup>8</sup> and muscle blocks receiving only one excitatory axon (but of the fast type) are also known<sup>9</sup>. Solely slow-innervated muscles are common in crustaceans. The extensor tibia muscle is innervated by one fast and one slow fibre, and, in the typical insect manner, the slow fibre innervates less than half of the muscle fibres.

Electrical responses of the extensor tibia are shown in Figs. 1A and B. It can be seen that the fast responses (B) are much larger than the slow responses (A), and are simple junction potentials with no spike components. They are thus comparable with the fast crustacean responses. The sizes of both fast and slow electrical responses are very variable from fibre to fibre in the same muscle block. The coxal muscles show electrical responses similar to the slow responses of the extensor tibia muscle, varying in size from fibre to fibre in the range 0.5–25 mV. The larger among these responses are much larger than those recorded from other insects, where most single slow responses can scarcely be seen, and few exceed 10 mV. The fast electrical responses of the extensor tibia may reach 50 mV, so both fast and slow responses are very comparable with those of crusta-

Fig. 1. The electrical response of the extensor tibia muscle of the mesothoracic leg of *Aeschna* to paired stimulation of the slow axon (A) and of the fast axon (B). There is no facilitation of the second response. Grid: horizontal, 5 msec, and vertical, 10 mV.

ceans. At any one place on a fibre successively evoked action potentials may vary greatly in size, by  $\pm 15$  per cent of the mean value; for a long series the sizes are normally distributed. Similar variation in size of slow junction potentials has been noted in the crayfish<sup>9</sup>.

The mechanical response of the extensor tibia to stimulation of the slow axon together with the simultaneous electrical activity of a single fibre is shown in Fig. 2. Very slight response to the first stimulus of the train (effectively a single stimulus) can just be detected in this figure. In other preparations a rather larger response was seen, but in all cases it was at least three orders of magnitude smaller than the corresponding twitch response to single fast stimulation. A striking feature of the mechanical response to repetitive slow stimulation is that there is a distinct response to each stimulus, almost invisible at the start of stimulation, but rapidly facilitating to give a distinctly pulsed tetanus. This can clearly be seen in

Fig. 2. Mechanical response of the coxal depressor of trochanter muscle of the mesothoracic leg of *Aeschna* to repetitive neural stimulation at 14/sec (A) and 25/sec (B) (upper traces) and the simultaneous electrical activity recorded intracellularly from one muscle fibre (lower traces).

Fig. 3. The relationship between the frequency of stimulation and the size of the second (○), third (▲) and fifth (●) individual mechanical responses evoked by a stimulus train. The size of the fourth response followed a pattern identical to the third, and all subsequent responses resemble the fifth. Mechanical response is expressed as a ratio to the first, very small response, to eliminate effects due to mechanical fatigue.

Fig. 2 in which the electrical activity of a fibre is recorded simultaneously. The degree of facilitation is dependent on two factors: the frequency of stimulation (that is how closely one stimulus follows another) and the size of the preceding response. This is illustrated in Fig. 3 which shows that any one response increases relative to the preceding one by a factor related approximately to the frequency. The individual mechanical responses, however, swiftly reach a maximum, so that after the third or fourth response there is little difference in size though summation continues. This is clearly illustrated by Fig. 2A.

This unusual mechanical response may well be a separate development among these insects which fulfils the function of a fast twitch system; this seems to be borne out by the fact that the slow-only innervated coxal muscle is much more accentuated than the extensor tibia, which is also innervated by a fast axon. The response, however, resembles that of crustaceans in one important respect. A "paradox phenomenon" has been reported<sup>10</sup> in certain decapod crustacea, where large slow electrical responses can be seen while there is very little mechanical activity. Fig. 2 shows that in dragonflies very different mechanical activity can accompany apparently identical action potentials. This is particularly clear in Fig. 2A. There is no electrical facilitation, and there is no continuous relationship between membrane potential and tension.

The mode of summation of the electrical responses, as seen in Fig. 2B, is comparable with the summation of both

Fig. 4. The relationship between the base depolarization evoked by neural stimulation at various frequencies in one fibre of the coxal muscle and the corresponding mechanical response of the whole muscle. The relationship between mechanical response and the base depolarizations of other fibres of the muscle gives similar patterns, but with greatly variable gradients. ○, Second response; ●, third response.

fast and slow crustacean responses<sup>7</sup>, in that within two or three potentials summation levels off, and thereafter action potentials originate from approximately the same membrane potential level. The difference between this level and the resting potential may be called the base depolarization. The principal difference between this and the crustacean response is the absence here of facilitation.

The base depolarization varies from fibre to fibre, in a way not dependent on the size of the action potential, although this must have some effect; it is partly dependent on the rate of decay of the action potential, which is also variable. The base depolarization of any fibre of a muscle block is directly and linearly related to the tension developed in the block, and also to the size of any one mechanical response in the chain (Fig. 4). This relationship holds however small or great the base depolarization, so again there is no one-to-one relationship between electrical and mechanical events. This relationship must be a pointer to some deeper membrane event, perhaps permeability changes to ions not responsible for the electrical action potential.

The dragonfly neuromuscular system is thus rather more like that of crustaceans than it is of other known insects, although it seems to have some specializations of its own. It is tempting to speculate that the system is more primitive than those of other insects in that the fast innervation and response are not present in some muscle blocks, and also that there is no active membrane response. As in crustaceans, the mechanical response to either fast or slow stimulation bears little obvious relationship to the action potential, because fast and slow responses are so alike and repetitive stimulation shows different mechanical responses responding to apparently similar slow action potentials. The relationship between slow mechanical responses and the greatly variable base depolarization may offer a pointer to some secondary membrane phenomenon, not directly reflected in the action potential, being at work. Further elucidation of these observations is being undertaken, and may throw light on both the paradoxical mechanical responses of some crustaceans, and on the connexion between excitation and contraction in arthropods generally.

I thank Dr D. W. Wood for criticizing the manuscript. This work was carried out while I was in receipt of an SRC Studentship.

### Stimulation of the Sodium Pump in Frog Bladder by Oxytocin

THE stimulating effect of the neurohypophyseal hormones on the transport of sodium ions across amphibian epithelial layers *in vitro* has been established for frog skin<sup>1</sup> as well as for toad bladder<sup>2</sup>. The site of action of the hormone is uncertain, however. Because the hormone increases the sodium pool in the bladder it has been suggested that the entry of sodium into the cells is facilitated by the hormone

acting at the mucosal membrane<sup>3</sup>. Similarly, with frog skin, it was inferred from the kinetics of the exchange of labelled sodium that the neurohypophyseal hormone enhanced the entry of sodium across the outer membrane into the epidermal cells<sup>4</sup>. In neither case was it suggested that the hormone stimulated the sodium pump directly, as the sodium pump is localized at the opposite face of the epithelial layer and expels sodium from the cells. Rather, this pump was supposed to become more saturated by the increase in concentration of intracellular sodium. Other workers<sup>5</sup>, however, have found that neurohypophyseal hormones recover the normal direction of the short-circuit current in frog skins bathed from the epidermal side by very dilute sodium sulphate solution. They have thus shown that an active step, whether localized at the outer or the inner border of the cells, must be directly stimulated by the hormone.

The aim of the present investigation is to show that whatever the character of sodium transport across the mucosal border and the action of the neurohypophyseal hormone on this transport, it is certain that the hormone directly stimulates the expulsion of sodium ions from the epithelial cells. In these experiments, the transport of sodium ions across the mucosal surface of epithelial cells of frog urinary bladder was prevented by covering the surface with liquid paraffin. Thus it was possible to separate the behaviour of the non-mucosal parts of the cell membranes for study and to examine the effects of oxytocin on this behaviour.

The frogs (*Rana temporaria*) were kept in the cold before the experiment, and killed by cutting the spine and pithing. The bladders, emptied by massaging the abdominal wall, were filled with liquid paraffin through a tube which was inserted into the cloaca. Two halves of the bladder were tied off separately, giving a control bag and an experimental bag. These bags were then incubated separately in aerated frog Ringer solution (m.equiv./l.: sodium, 114.5; potassium, 5.0; chlorine, 119.0; bicarbonate, 2.5; calcium, 1.0), the experimental medium containing 50 mU of synthetic oxytocin ('Spofa')/ml. After incubation for 25–30 min at room temperature (20–30° C), the bags were cut, the tissue thoroughly blotted on filter paper and weighed on a torsion balance. The tissue was then dried at 95° C overnight, weighed and its water content estimated as kg of water/kg of dry solids. The solids were extracted in 0.1 molar sulphuric acid for 5 days, and the sodium and potassium contents were determined by flame photometry of the extract using the EEL apparatus. Chloride content was determined by potentiometric titration of the extract according to Sanderson<sup>6</sup>. The results were expressed/kg of dry solids and are summarized in Table 1. Because the results were obtained in pairs, the standard deviation of the mean of the differences between the paired values was used in the *t* significance test.

It can be seen that oxytocin produces a significant loss of chloride anions and highly significant ( $P < 0.001$ ) losses of water and of sodium and potassium cations. The loss of cations is on average greater than that of chloride, but the difference is not significant, being  $20.5 \pm 11.4$  ( $n = 25$ ),  $0.05 < P < 0.1$ .

Other experiments were carried out to estimate the proportion of the observed changes that were respectively intracellular and extracellular. For this estimation, the inulin space was measured for the preparation with oil on the mucosal side, and an estimate made of the effect

Table 2. EFFECT OF OXYTOCIN ON THE INULIN ACCESSIBLE AND INULIN INACCESSIBLE WATER CONTENT IN FROG BLADDERS FILLED WITH LIQUID PARAFFIN

	Controls	Oxytocin (50 mU/ml.)	Significance level
Water accessible to inulin (kg/kg DS)	$1.65 \pm 0.08$	$1.47 \pm 0.08$	$0.1 < P < 0.2$
Water inaccessible to inulin (kg/kg DS)	$1.63 \pm 0.10$	$1.30 \pm 0.09$	$P < 0.02$

DS, Dry solids.

of oxytocin on this space. The inulin spaces, calculated as a per cent of wet weight of bladder tissue, were  $38.47 \pm 1.75$  ( $n = 28$ ) for the control and  $39.09 \pm 2.00$  ( $n = 28$ ) for the half bladder treated with oxytocin. The amounts of inulin accessible to water and inulin inaccessible to water were calculated (Table 2) from the estimates of the inulin space and those of the wet weight/kg of dry solids. The latter were determined in the first series of experiments ( $n = 25$ ) as  $4.28 \pm 0.097$  in the controls and  $3.77 \pm 0.089$  in the half bladders treated with oxytocin. The standard errors of the means were combined according to the expression

$$\sigma_{xy} = \sqrt{(\bar{y}^2\sigma_x^2 + \bar{x}^2\sigma_y^2)}$$

where  $\bar{x}$  and  $\bar{y}$  are the mean values and  $\sigma_x$  and  $\sigma_y$  the corresponding standard errors. It will be seen that the change in the "extracellular" water is not significant, whereas the change in the "intracellular" water is probably significant,  $P < 0.02$ . The hormone seems to lower the concentration of sodium from 30 m.equiv./l. to 19 m.equiv./l. and raise that of potassium from 133 m.equiv./l. to 150 m.equiv./l. These changes can be seen if the intracellular concentrations of sodium and of potassium in control bladders and bladders treated with oxytocin are calculated from the mean values given in the two tables.

These results suggest that the expulsion of sodium is stimulated by the neurohypophyseal hormone and the loss of sodium chloride is followed by a loss of osmotically driven water. Thus potassium chloride is concentrated and also diffuses out of the cells to some extent.

### Changes in Plasmalogen Content of Human Heart and Skeletal Muscle with Age and Development

The proportion of plasmalogen to total phospholipid in mammalian heart muscle seems to depend on both the age and species of the animal, with the choline plasmalogen (glycerol-2-acyl-1-alkenyl-3-phosphorylcholine) showing the most marked variations<sup>1-3</sup>. Species differences in the plasmalogen content of skeletal muscle also seem to be considerable and on the basis of analyses of monkey muscle, primate skeletal muscle has been suggested to be considerably richer in plasmalogens than tissue from other species, such as the rabbit<sup>4</sup>. Some of our analyses of mature and immature human muscle have shown that maturational changes, somewhat similar to those occurring in heart muscle, also take place in skeletal muscle. In addition they suggest that the plasmalogen content of

Table 1. EFFECT OF OXYTOCIN (50 mU/ml.) ON WATER AND ION CONTENTS IN FROG BLADDERS FILLED WITH LIQUID PARAFFIN (25 PAIRS)

	Controls	Oxytocin (50 mU/ml.)	Significance level

Chlorine molar equivalent/kg DS	296.0	249.6	$P < 0.001$

DS, Dry solids.

mature human skeletal muscle is similar to that of monkey muscle.

Specimens of mature and foetal human heart and skeletal muscle were frozen in liquid nitrogen and crushed into a pellet which was then extracted by homogenizing with chloroform-methanol (2:1). The resultant extract after treatment with chloroform-methanol (2:1) containing 4 per cent water to precipitate protein<sup>5</sup> was washed with 0.1 molar potassium chloride<sup>6</sup>, evaporated to dryness and redissolved in a suitable volume of dry chloroform-methanol (2:1) for chromatography. The extracts were stored at -25° C until analysis. Thin-layer chromatography on silica gel was carried out by the two dimensional technique of Owens<sup>7</sup> and the phosphorus in the separated zones was estimated by a slight modification of Bartlett's method<sup>8</sup>.

Data for choline and ethanolamine phospholipid (excluding sphingomyelin) are presented in Tables 1 and 2. Two things are apparent: (a) human heart muscle contains rather less total choline phospholipid at all stages of development than does skeletal muscle; and (b) despite the differences between the two tissues the same trend of increasing choline plasmalogen can be seen. The data also suggest that there is an appreciable increase with development in the ethanolamine plasmalogen of skeletal muscle, but at the earliest foetal age studied, about 10 weeks, nearly half the ethanolamine fraction exists in the plasmalogen form. In heart muscle, on the other hand, the proportion of ethanolamine plasmalogen does not show any consistent change with development.

Table 1. PLASMALOGENS IN HUMAN HEART MUSCLE

Tissue	Age	Choline phospholipid		Ethanolamine phospholipid	
		Plasma- log-en	CP % total lipid phosphorus	Plasma- log-en	EP % total lipid phosphorus
Foetal	c. 10 weeks	n.d.	38	51	22
Foetal	c. 13 weeks	n.d.	43	52	30
Foetal	c. 15 weeks*	7, 4	47, 45	52, 54	30, 27
Stillbirth	—	14	40	60	25
PM	22 months	25	37	45	32
PM	38 yr	36	40	49	27
PM	65 yr	48	40	59	27

EP, ethanolamine phospholipid phosphorus; CP, choline phospholipid phosphorus (excluding sphingomyelin); n.d., not detected ( $\leq 5$  per cent) possibly because of a small amount of material available; PM, post-mortem.

Biopsy	27 years	19	51	63	24

Abbreviations are as in Table 1.

\* Estimations of three foetuses.

† Psoas muscle.

The choline plasmalogen content of human heart muscle increases after birth and possibly even in the period after maturity, as the result for the 65 yr old individual suggests. In the case of skeletal muscle, however, the present results are inconclusive because the analyses were not all carried out on the same muscle, and we have some evidence that mature human muscles may differ in their content both of choline and ethanolamine plasmalogen (unpublished analyses of biopsy material); Masoro *et al.*<sup>4</sup> found considerable differences between monkey gastrocnemius and soleus muscle in this respect. On the other hand the tissue derived after death from 5 month old and 13 month old infants was psoas muscle in each case and here there does appear to be appreciably more plasmalogen in the psoas muscle of the older child.

It is interesting that whereas choline plasmalogen as a proportion of choline phospholipid increases during foetal development in heart muscle at least for some time after birth, total choline phospholipid phosphorus as a percentage of tissue phospholipid phosphorus remains fairly constant. Kiyasu and Kennedy<sup>9</sup> suggested that the enzyme system which synthesizes plasmalogens from cytidine diphosphate choline and plasmalogenic diglyceride may be the same as that responsible for the formation of the corresponding diacyl phospholipids from cytidine diphosphate choline and the diacyl glyceride. If this is the case then the observed increase in plasmalogen may reflect increased synthesis of plasmalogenic diglyceride as development proceeds, leading to the formation of more plasmalogen by virtue of the increased precursor concentration.

In the case of heart muscle a direct relation has been reported between tissue plasmalogen and body surface area for various species<sup>1</sup>. If this is correct then the changes occurring during development may simply reflect an increase in size. These data<sup>1</sup>, however, are in conflict with other data<sup>2</sup> which indicate considerably larger plasmalogen concentrations in the heart muscle of smaller mammals, for example, mouse and cat. Furthermore, the greatest plasmalogen concentrations were found in the heart of a small mammal, the guinea-pig. Our own analyses of mouse heart gave for plasmalogen expressed as moles per cent of total phospholipid, values of 10 per cent and 13 per cent respectively on two batches of pooled tissue; a result which is in good agreement with that of Spanner<sup>3</sup> and which conflicts with the value of 4.4 per cent found by Thiele *et al.*<sup>1</sup>. Consequently there seem to be other factors, apart from body surface area, which influence the concentration of plasmalogen.

Our results for human skeletal muscle confirm the observation of Masoro *et al.*<sup>4</sup> that primate muscle is rich in plasmalogen. Whether, as these authors suggest, it is remarkable in this respect may be questionable, because, for example, ox muscle seems to contain at least as much plasmalogen as human and monkey muscle<sup>10</sup>. Furthermore, Masoro *et al.*<sup>4</sup> compared their total molar ratio of plasmalogen : lipid phosphorus for monkey muscle of 0.25 with a figure of 0.11 for rabbit muscle<sup>11</sup>, although this latter figure refers only to choline plasmalogen. Consequently, the total ratio of plasmalogen : lipid phosphorus rabbit muscle is likely to be considerably greater than this. Nevertheless, compared with some species, such as sheep (molar ratio 0.10 (ref. 12)), and the mouse (molar ratio 0.08, calculated from the results of Hughes<sup>13</sup> and Owens<sup>7</sup>), the plasmalogen content of mature human and monkey muscle is large.

### The Salt Gland in a Sea Snake (*Laticauda*)

ONE marine lizard and several marine turtles possess salt glands capable of secreting highly concentrated solutions of sodium chloride<sup>1</sup>. The salt gland appears to be of adaptive advantage to reptiles exposed to electrolyte loads, because the kidney is unable to excrete urine hyperosmotic to the blood. A sea snake (*Laticauda semifasciata*) follows the general pattern of ionic regulation found in marine turtles and a marine lizard<sup>2</sup>. The work reported here was designed to identify the salt glands of *Laticauda semifasciata* and compare it with the homologous gland of another sea snake, *Pelamis platurus*. *Laticauda* excretes a relatively dilute urine (7–148 mmolar sodium) from the kidney and a concentrated sodium chloride solution (380–625 mmolar) orally<sup>2</sup>. The rate of excretion of extrarenal sodium chloride increases to as much as 72  $\mu$ moles/100 g/h after injection of a sodium chloride or sucrose load<sup>2</sup>. This response must be due to a salt gland. In all lizards the salt gland is the nasal gland; secretions pass from the nasal passage out through the external nares<sup>1,3,4</sup>. In turtles, salt gland secretion elaborated by the Harderian gland is discharged under the eyelid<sup>1</sup>. Crocodiles may have a similar route of extrarenal electrolyte excretion<sup>2</sup>.

The genus *Laticauda* is usually regarded as less specialized for marine life than *Pelamis*<sup>5</sup>. It is coastal in distribution and partly terrestrial in habitat<sup>5</sup>. Thus *Laticauda* is less restricted to the sea than *Pelamis*, a pelagic form. This difference in habitat might be reflected in the relative size of the salt gland and the ability of the two genera to excrete salt loads extrarenally.

One *Laticauda* head was preserved in Bouin's solution, decalcified in sodium citrate and formic acid, dehydrated, and cleared in cedar wood oil for two weeks. After embedding in paraffin, serial sections of the whole head were cut at 10 $\mu$ . The sections were stained with Masson's trichrome. The body weight of this snake was 300 g. The tissue believed to be the salt gland was removed from another freshly killed snake and preserved in cold buffered formalin. After embedding and sectioning at 5 $\mu$ , the

sections were stained with toluidine blue (pH 2.0), haematoxylin and eosin, and periodic acid-Schiff (PAS) reagent before and after ptyalin (salivary) digestion. A gross morphological comparison was made between the cephalic region of *Laticauda* and that of *Pelamis platurus*. Dr J. Peters kindly provided the specimen of *Pelamis*. Other specimens are in the collection of Dr A. M. Taub.

Because fluid from the salt gland had been collected from the tip of the mouth between the rostral and mental scales<sup>2,6,7</sup>, attention naturally focused on the glands draining into this region. Taub<sup>6</sup> has recently reviewed the distribution of the cephalic glands in snakes, which can be divided into oral and non-oral types. The latter category consists solely of the nasal and Harderian glands and the venom gland is reported to be the only serous oral gland in sea snakes. The histology and distribution of the sublingual and supralingual glands are unknown in sea snakes. Thus the only major serous glands draining directly into the oral cavity of snakes are the Harderian glands found in the post-orbital region, and the venom glands. The nasal glands have only a very indirect connexion with the oral cavity via the nasal passage. After dissection of the muscles of the head (see Haas<sup>9,10</sup> for details of the anatomy of head muscles in the sea snake), a very small Harderian gland was found anterior and deep to the m. levator pterygoidei (Table 1). This gland lies almost in the mid-line. Comparison with a specimen of *Pelamis platurus* revealed that *Pelamis* did not have a grossly discernible Harderian gland. No grossly distinguishable nasal gland was found in the nasal region of *Pelamis* (Table 1). This confirmed the results of Kathener<sup>11,12</sup>. *Laticauda* was found to have a well developed nasal gland (Fig. 1). We were unable to collect any fluid from the nasal vestibule of *Laticauda* after salt loading. The absence of nasal and Harderian glands in *Pelamis*, the pelagic Hydrophiid, supported the conclusion that in sea snakes these glands are not the salt glands.

Table 1. THE PRINCIPAL NON-SALIVARY GLANDS OF *Laticauda* AND *Pelamis*

	Coastal <i>Laticauda</i>	Pelagic <i>Pelamis</i>
Harderian	Yes	No
Nasal	Yes	No
Natrial	Yes	Yes

Fig. 1. Cross section of the left side of the head of *Laticauda semifasciata* ( $\times 8.5$ ). a, Anterior to the premaxilla showing the main body (mb), lateral branch (lb), tubules of the natrial gland (t), nasal capsule (nc) and external nares (en). b, Anterior to Jacobson's organ showing the duct of Jacobson's organ (djo), duct of the natrial gland opening into the mouth (d), end of lateral branch of natrial gland (lb), posterior nasal vestibule (nv), maxilla (m), nasal gland (ng), and nasal bone (n). (Drawn by R. D. Chambers.)

In an attempt to find additional oral glands a median incision was made, bisecting the interpalatine groove of a preserved *Pelamis* head. An azygous, pear-shaped gland was revealed anterior to the choanae. This new gland was heavily encapsulated in connective tissue, and about 5 mm long (Fig. 2). Dissection of *Laticauda* revealed a

Fig. 2. Palatal view of the nasal region (rostral on right) of *Pelamis platurus* showing the fang (f), palatine tooth row (p), natrial gland (natg), interpalatine groove (ipg), interpalatine ridge (ipr), and internal choanae (ic). There is an incision in the midline (x) bisecting the palate and natrial gland. (Drawn by R. D. Chambers.)

much smaller gland in the same region (Fig. 3). Serial sections of a skinned head of *Laticauda* were prepared. A scale model of the gland was reconstructed by tracing low power projections of every fifth section from a viewing screen on an 'AO' trinocular microscope. The tracings were pasted on mounting board of appropriate thickness and glued together. The *Laticauda* gland has an unusual shape (Fig. 3). It apparently is secondarily fused as shown by the bilobed anterior tip, and the paired lateral ducts. There is a main body about 0.6 mm long, two posterior lateral branches about 1 mm long, and paired ducts emptying into the interpalatine groove. There are six apparently blind tubules running posteriorly in the midline from the main, medial portion of the gland. The main body of the gland underlies the premaxilla; the lateral branches extend to the level of the medial edge of the maxilla. The ducts run medially for about 0.5 mm before turning posteriorly again to empty into the connective tissue which makes up the posterior boundary of the interpalatine ridge. The ducts empty anterior to the openings of the vomeronasal organ. Secretory fluid could easily be pushed down the interpalatine groove to the outside by the tongue. Salt gland fluid was collected from the tip of the mouth when the tongue was extended<sup>2</sup>. The gland is apparently a multilobulate tubuloacinous gland. Because of the complexity of the convolutions it was not possible to trace every lobule to the duct. The glandular tissue is fairly diffuse, and the majority of the tubules are clearly separated by connective tissue. The gland is well innervated, but the nerves have not been traced to their origin. The gland cells are PAS positive, and remain so after ptyalin digestion. They show metachromasia with toluidine blue, indicating that polysaccharides other than glycogen are present.

Fig. 3. Palatal view of the nasal region (rostral on right) of *Laticauda semifasciata* with the superimposed outline of the natrial gland. Label as in Figs. 1 and 2. (Drawn by R. D. Chambers.)

The oral epithelium of *Laticauda* is a stratified squamous epithelium. This is in sharp contrast to the simple mucous epithelium of other snakes which have been studied<sup>8</sup>. The stratified squamous epithelium in *Laticauda* is thickest on the medial surface of the interpalatine ridge, and becomes progressively thinner towards the oesophagus. The presence of a thickened, stratified, squamous epithelium near the ducts of this new oral gland may result from the presence of hyperosmotic fluid in this region.

No gland in this position has previously been described in snakes. Because this may be an extrarenal salt gland, we have named it the natrial gland (*natrium* is Latin for sodium). The large size of the natrial gland in *Pelamis* indicates that secretory activity may be greater than in *Laticauda*. There is no evidence that sodium rather than

chloride is actively transported by the gland. The homology of the gland is uncertain, but it seems likely that it is derived from the premaxillary gland. Alternatively, the vomerine gland may be involved, but it is found in this region only in lizards<sup>13</sup>. Without more adult and embryonic material it is impossible to assign a definite homology.

### Maturity at Birth and Adult Protein Bound Iodine

Few adult biophysiological measurements can be traced back to the neonatal state. In a series of twenty-three pairs of monozygotic twins studied at the Clinical Center at the National Institutes of Health, Bethesda, adult protein bound iodine (PBI) was found to be directly related to weight at birth ( $r = 0.58$ ,  $P < 0.001$ ) (Fig. 1).

The most widely used measure of foetal maturity is the weight at birth<sup>1</sup>. Measurements of PBI and of the iodine

Fig. 1. The relationship between adult protein bound iodine (PBI) and weight at birth for 46 monozygotic twins. The solid line represents the least squares linear fit.  $PBI (\mu g \text{ per cent}) = 2.7424 + 1.1805 \text{ birth weight (kg)}$  ( $N = 46$ ). The correlation coefficient is  $+0.58$ ,  $P < 0.001$ . The broken line represents the least squares linear fit for 129 neonates studied by Marks and Man<sup>2,4</sup>.  $BEI (\mu g \text{ per cent}) = 3.3217 + 1.8963 \text{ birth weight (kg)}$ . The correlation coefficient is  $+0.65$ ,  $P < 0.001$ .

that can be extracted with butanol (BEI) are higher in infants heavier in weight at birth and lower in infants of low birth weight even though PBI or BEI in the neonate undergo rapid changes during the first year of life<sup>2,3</sup>.

A re-analysis of the neonatal data of Marks and Man<sup>2</sup> and Man<sup>4</sup> has demonstrated that BEI in the neonate is directly correlated with birth weight ( $r = +0.65$ ,  $P < 0.001$ ,  $N = 129$ ).

Protein bound iodine has long been used as a clinical indication of current thyroid function and as an indirect measure of the current metabolic state of the body<sup>5</sup>. While the range of PBI for large samples of normal individuals extends from 3.1 to 7.7  $\mu\text{g}$  per cent (95 per cent limits of confidence)<sup>6</sup>, test/re-test variance over time for individuals has been noted to be less than variance between individuals<sup>7</sup>.

The normal range of PBI and BEI in the neonate is higher than in the adult<sup>8</sup>. Provided that artefacts are eliminated, PBI and BEI can be used as equivalent measures of thyroid activity<sup>9</sup>. As can be seen in Fig. 1, the similarity of the lines of least squares linear fit for each study—that of PBI in adults and that of BEI in the neonates—suggests a biological constancy between the degree of maturity as estimated by weight at birth and thyrometabolic function in the neonate and adult as measured by protein bound iodine.

The series of twins are part of an investigation of schizophrenia now being carried out at the National Institutes of Health<sup>10,11</sup>. Zygosity was estimated by serological methods. In twelve of the fourteen pairs where one twin had been diagnosed as schizophrenic, the twin of lower birth weight was the twin who subsequently developed schizophrenic symptoms<sup>12</sup>. The direct relation between PBI and birth weight is significant with ( $r = +0.58$ ) or without ( $r = +0.65$ ) the schizophrenic subjects. This indicates the relation in the adult is not dependent on the presence of schizophrenia.

All determinations were made as coded blind samples by Bio Science Laboratories, Los Angeles, California. Duplicate determinations for the last twelve individuals studied had a mean difference of  $0.17 \mu\text{g}$  per cent  $\pm 0.03$ . Test/re-test for PBI for seven subjects gave similar values (mean difference  $0.47 \mu\text{g}$  per cent  $\pm 0.10$ ) and the same intrapair relation was found. Correlations were obtained by Pearson product-moment method. Possible sources of error due to inaccuracies in the reported birth weights, variance of PBI as a result of diurnal and daily cyclical fluctuation, changes arising from increased binding related to the menstrual cycle or contraceptive drugs, effects of anquillizers, artefactual effects of organic and inorganic acids and variations due to differences in environmental temperature have been evaluated and do not appear to terminate the foregoing correlation.

In the adult series of monozygotic twins, when each twin was compared with his co-twin, the within pair variance for PBI was  $0.81 \mu\text{g}$  per cent, while estimates of variability between pairs was  $0.66 \mu\text{g}$  per cent. Because variance within the pairs is greater than between pairs, the factor of genetic similarity does not seem as important determinant for PBI as individual non-genetic differences. One source of the large variance in PBI values between individuals may therefore result from intrauterine factors, perhaps the intrauterine nutritive experience which may have determined in part the size of the foetus. It seems, however, that it is not just the size of the foetus at birth, but the size of the foetus at birth that is important in establishing adult concentrations of bound thyroid hormone.

If PBI does reflect the level of free metabolically active hormone, it will be necessary to re-explore adult differences in somatic growth and central nervous system development in relation to the intrauterine experience, fetal maturity and neonatal thyrometabolic state.

We thank Drs J. Tupin, L. Mosher and A. Hoffer for their help in the implementation of this study, and Dr

Samuel Greenhouse, Gabrielle Bachman and Karen Pettigrew for their statistical and technical assistance.

## CYTOLOGY

### Elimination of Ribosomes during Meiotic Prophase

At the conclusion of the meiotic divisions in the angiosperm anther, the cytoplasm of each mother cell is partitioned more or less equally between the four daughter spores, which then become isolated from each other by the formation of the callose tetrad wall. As a possible determinant of the pattern of gene expression in the gametophyte, the state of the meiocyte cytoplasm at the time of cleavage is of some significance. Is the cytoplasm bequeathed simply a sample of that of the original diploid archesporial cell, or does some metamorphosis occur concurrently with meiosis? An answer to this question could cast light on the control of the sporophyte-gametophyte alternation, and be relevant also to the problem of cytoplasmic inheritance.

Changes in RNA content and composition and in ribosome populations have been studied in the meiocytes of two liliaceous species, *Lilium henryi* and *Trillium erectum*. For the direct determination of the quantity and base composition of meiocyte RNA, the ultramicrochemical methods of Edström were used<sup>1</sup>. Individual meiocytes were isolated from sections in a de Fonbrune oil chamber, using a micromanipulator<sup>2</sup>. The callose meiocyte walls were removed, and RNA was extracted with ribonuclease. Total amounts of RNA were estimated by redissolving the extracts and photographing the droplets obtained, together with a reference system, in ultra-violet light at 265 m $\mu$ . For base analysis, the RNA extracts were hydrolysed in 4 normal hydrochloric acid, applied to a cellulose fibre, and the bases separated by microphoresis. After separation, the bases were measured by means of photometry in ultra-violet light at 265 m $\mu$ . Quantities as small as 150  $\mu\text{g}$  of RNA can be analysed in this way, so that determinations could be made on as few as three isolated meiocytes. Contamination with tapetal or other extraneous cells is wholly excluded by the method.

Material of *L. henryi* for electron microscopy was fixed in 1.5 per cent glutaraldehyde, post-fixed in 1 per cent buffered osmium tetroxide and embedded in 'Araldite'. Because apparent ribosome density in electron micrographs is related to section thickness, sections uniformly showing silver/gold interference colours were used. A grid of 2 cm squares was placed over each ( $\times 46,000$ ) print, and

ten squares were selected using a table of random numbers, passing over squares happening to fall over organelles or the nucleus. The ribosomes in each square were then counted. Three micrographs from each meiotic stage were surveyed, giving 30 square-counts/stage. The means obtained refer to the number of ribosomes present in standard volumes of cytoplasm, and to provide a more precise indication of variations in the population/cell correction for volume change would be required. In *Lilium*, as in *Zea mays*<sup>3</sup>, however, there is little growth of the meiocytes from mid-prophase to the close of the meiotic divisions.

Meiocyte RNA contents are shown in Figs. 1 and 2. The curves for the two species agree in showing a dramatic drop in total acetic-alcohol fixed RNA in the interval pachytene-diplotene-diakinesis, followed by a rise to

Fig. 1. *Lilium henryi*. Total RNA/meiocyte or dyad at various times during meiosis. Six to ten replicate samples of three cells estimated for stages leptotene to metaphase I; ten replicate samples of six dyads for metaphase II. L, leptotene; Z, zygotene; P, pachytene; D/D, diplotene-diakinesis; MI, metaphase I; MII, metaphase II. Vertical lines indicate  $\pm$  standard error.

Fig. 2. *Trillium erectum*. Total RNA/meiocyte or dyad at various times during meiosis. Ten replicate samples of three cells estimated for leptotene-zygotene and metaphase I; nine of three cells for zygotene; ten of six cells or dyads for pachytene, diplotene-diakinesis and metaphase II. Stages as in Fig. 1, except that L/Z indicates cells transitional between leptotene and zygotene. Vertical lines indicate  $\pm$  standard error.

Fig. 3. Mean numbers of ribosomes/unit volume of cytoplasm estimated from electron micrographs in the way indicated in the text. Meiotic stages as in Fig. 1 with the addition of PL, pre-leptotene, the separation of diplotene and diakinesis, and the inclusion of AI, anaphase I. Vertical lines indicate  $\pm$  standard error.

Fig. 4. Pre-leptotene cytoplasm, showing numerous ribosomes. M, mitochondrion.

metaphase I. Total RNA content is higher in the large *T. erectum* cells than in those of *L. henryi*, but the proportionate fall from zygotene to diplotene-diakinesis is similar.

The electron micrographic evidence indicates that the decline in RNA in mid-prophase is associated with reduction in the ribosome population. Fig. 3 shows striking fall in numbers in each unit volume to a minimum again in the interval pachytene-diplotene-diakinesis followed by a rise to anaphase I, the latest stage for which

Fig. 5. Pachytene cytoplasm, denuded of ribosomes. The photograph shows two adjacent meiocytes connected by a broad cytoplasmic channel. W, Primary meiocyte wall (cellulose); C, special meiocyte wall (callose); P, site of a severed plasmodesma.

observations were made. The remarkable contrast between the pre-leptotene and the diplotene cytoplasm is brought out by Figs. 4 and 5. Few ribosomes were discernible at all in the cytoplasm of diplotene and diakinesis cells, but small aggregates were usually apparent within the multi-membraned bodies which replace the plastids during this part of the meiotic prophase.

Adenine/guanine ratios for total cell RNA at different meiotic stages are set out in Table 1 for *L. henryi* and *T. erectum* with the corresponding ratios for the DNA of the two species. In each species there is a significant increase in the A/G ratio during the period of least RNA content. The ratio shifts towards that characteristic of the DNA, and in *L. henryi*, where the A/G ratio of the DNA is greater than in *T. erectum*, the upward shift is proportionately greater.

Table 1. ADENINE/GUANINE RATIOS FOR TOTAL CELL RNA OF *Lilium henryi* AND *Trillium erectum* DURING MEIOSIS

<i>L. henryi</i>			
Meiotic stage	Adenine/Guanine	Units/estimation	Replicates
Zygotene	0.99 ± 0.02	3 cells	7
Pachytene	1.24 ± 0.04	6 cells	10
Diplotene-diakinesis	1.67 ± 0.10	6 cells	7
Metaphase II–telophase II	0.95 ± 0.04	6 dyads	8
DNA	2.04		120
<i>T. erectum</i>			
Meiotic stage	Adenine/Guanine	Units/estimation	Replicates
Leptotene–zygotene	0.85 ± 0.03	3 cells	17
Diplotene	0.96 ± 0.02	6 cells	7
Metaphase II–telophase II	0.87 ± 0.04	6 dyads	13
DNA	1.48		60

These observations answer the question posed in the introductory paragraph: the cytoplasm received by the spores is not merely a portion of that present in the mother cells, for a drastic reorganization occurs immediately before the cleavage. Speculation on the significance of this fact is perhaps premature, but it may be noted that

wholesale elimination of the ribosomes of the diploid cell might be understandable if it were a requirement for the initiation of the haploid phase that a new protein-synthesis system should be established. This could be a device ridding the cell of long-lived messengers, or for restoring to a norm whatever controls of gene action transmissible through mitotic cycles may be effective in the diploid cell lineages<sup>4</sup>.

Among the questions raised by these findings are the location and nature of the residual RNA present at the time of the elimination of ribosomes. That its base composition is closer to that of the DNA of the species concerned than to that of the ribosomes may indicate a nuclear site; but the seeming persistence of small clusters of ribosome-like bodies in the modified organelles may be significant.

A further problem is the source of the ribosomes that populate the cytoplasm anew by metaphase I. The timing of the principal increase appears to be post-diakinesis—at a period, that is, when no nucleolus is present. Incorporation experiments have not given evidence of any massive RNA synthesis during the interval in question<sup>5,6</sup>. This is, however, perhaps to be expected, because the meiocytes and later the spores in the tetrad form closed systems after the sealing of the callose wall<sup>7,8</sup>, and presumably the new synthesis is largely at the expense of the pool of break-down products released by the degeneration of the ribosomes originally present.

## BIOLOGY

### Effect of Temperature on the Selective Value of Genotypes of the Copepod *Tisbe reticulata*

IN the Lagoon of Venice, the harpacticoid copepod *Tisbe reticulata* shows a striking polychromatism which is controlled by three alleles at the same locus, *VV*, *VM* and *v*. The first two, dominant over the common recessive *v*, are responsible for the forms violacea and maculata, respectively, whereas the homozygote *vv* is responsible for the form trifasciata. The alleles *VV* and *VM* are co-dominant and therefore the heterozygote *VV VM* is phenotypically recognizable. It has been shown that this polymorphism is adaptive and balanced, and, in most cases, maintained

Table 1. PHENOTYPE DISTRIBUTIONS IN SPRING AND SUMMER SAMPLES OF THE COPEPOD *Tisbe reticulata*

Population			Phenotypes				Total	$\chi^2$ and $P$
			Maculata	Violacea	Maculata-Violacea	Trifasciata		
Spring	$P$	Observed	36	34	5	41	116	$\chi^2 = 2.54$ $P > 0.3$
		Expected	31.2	30.4	7.8	46.6		
	$F$	Observed	1,370	1,292	508	2,156	5,326	$\chi^2 = 123$ $P < 0.001$
		Expected	1,421	1,339.5	329.7	2,235.8		
Summer	$P$	Observed	27	52	8	68	155	$\chi^2 = 0.46$ $P > 0.9$
		Expected	29.1	49.1	8.3	68.5		
	$F$	Observed	1,693	1,931	597	3,729	7,950	$\chi^2 = 150.6$ $P < 0.001$
		Expected	1,746.6	1,991.5	367.3	3,844.6		

by the greater survival value of the heterozygotes compared with the homozygotes<sup>1</sup>.

There is experimental evidence that salinity may be a selective environmental factor. In fact, the various forms show different relative abilities to tolerate fluctuations in salinity<sup>2,3</sup>.

Recent observations suggest that water temperature may also act as a selective factor to an even greater extent than salinity. The experiments reported here have been carried out, both in natural and laboratory populations, to provide more detailed information on the action of this important ecological parameter.

In the Lagoon of Venice the species can be found only in late spring and in summer, and practically disappears in autumn and winter. Only on a few occasions have we been able to collect samples of *Tisbe* sufficiently large to permit estimates of gene frequencies. A first sample of 116 females was collected in May, when the water temperature was about 18°C. Very few males have been collected, and as they are not easily classifiable they were not considered.

The females of this sample, which we shall refer to as the parental population ( $P$ ), were individually transferred into single culture vessels in a constant temperature room at 18°C, according to the method usually followed in our laboratory for rearing copepods<sup>2</sup>. They were left in the vessels until they had produced two egg sacs each, in order to get a sufficient number of offspring for genetic analysis.

The first generation, or  $F$  population, consisted of 5,326 individuals of both sexes. By analysis of this first generation—and, where necessary, of the next two generations—it was possible to identify the genotypes of each mother as well as the type of cross. This permitted us to infer also the genotypes of the male parents although not necessarily their actual frequency in nature. The gene frequencies in the  $P$  population were thus counted directly, whereas in the  $F$  population they were calculated by applying the Hardy-Weinberg formula.

A second sample of 155 females was collected in the same area in July, when the water temperature was about 24°C. Their first generation in the laboratory consisted of 7,950 individuals of both sexes.

The distributions of phenotypes in the spring and summer population samples are given in Table 1. The data show that in the  $P$  populations of both samples there is quite good agreement between the observed distributions of the various phenotypes and those expected on the basis of the Hardy-Weinberg. In the  $F$  populations there is, instead, a strong disagreement between the observed and the expected distributions, chiefly caused by the excess of the heterozygotes violacea-maculata.

The results of previous experiments demonstrated that the excess of heterozygotes increases with the degree of crowding in the cultures. Actually, the  $F$  populations have developed in very crowded conditions, principally because they derive from females collected in the wild, which usually lay more eggs.

The gene frequencies of spring and summer samples are shown in Table 2. A comparison between the gene frequencies of the two parental populations indicates a

slight increase of  $VV$  and  $v$ , and a strong decrease of  $VM$  in the hot season. The difference is statistically significant ( $\chi^2 = 4.114$ ,  $P < 0.05$ ) only so far as  $VM$  is concerned.

Table 2. GENE FREQUENCIES IN SPRING AND SUMMER SAMPLES OF THE COPEPOD *Tisbe reticulata*

Population		Gene frequencies (per cent)		
		$VM$	$VV$	$v$
Spring (18°C)	$P$	18.5	18.1	63.4
	$F$	18.1	17.1	64.8
Summer (24°C)	$P$	12.9	20.6	66.5
	$F$	14.3	16.1	69.5

The environmental factor which shows the greatest change from spring to summer in the waters of the Lagoon of Venice is temperature. Salinity, nutrients and other factors, although fluctuating, do not undergo consistent changes in the same period. We therefore assumed that the observed changes in gene frequencies might be caused by a change in the temperature of the water.

A further suggestion that temperature could be important in this respect comes from the fact that the gene frequencies of the  $P$  and  $F$  populations do not seem to differ from each other in the spring sample, whereas they do differ in the summer sample. In the spring sample the  $F$  population developed in the laboratory at the same temperature (18°C) as the parental population in the wild; however, in the summer sample the parental population developed at 24°C and the offspring at 18°C.

Of the three genes considered,  $VM$ , which shows the greatest difference in frequency between the spring and the summer samples, seems to be more affected by temperature. Its selective value seems to be greater at lower temperatures, and vice versa.

The validity of this working hypothesis is supported by the results of experiments carried out with laboratory populations, maintained by a method the details of which have been given before<sup>4</sup>. The experiments have been made with populations in which only the genes  $VV$  and  $VM$  were present. One population was started with 80 per cent  $VV$  and 20 per cent  $VM$  and another one with 80 per cent  $VM$  and 20 per cent  $VV$ . Both populations were kept at 18°C and sampled from time to time, with an average interval of 20 days, during a period of 250 days, corresponding to about seventeen generations<sup>5</sup>.

Two other populations, with the same initial composition as the first two, have been kept at 23°–24°C and sampled at slightly shorter intervals for a period of 230 days which, at this temperature, corresponds to about twenty-four generations<sup>6</sup>. The populations maintained at 18°C reached equilibrium after about fifteen generations, at a frequency of the gene  $VM$  of about 60 per cent. The populations kept at 23°–24°C also reached equilibrium after fifteen generations, but in this case the equilibrium frequency of  $VM$  was of about 40 per cent.

These experiments show that the adaptive value of the gene  $VM$  can be influenced to a large extent, both in natural and experimental populations, by temperature. This is a result similar to those obtained in the study of chromosomal polymorphism of certain species of *Drosophila*.

## Food-chain Toxicity of Systemic Acaricides to Predaceous Mites

It is considered that one of the theoretical advantages of systemic materials applied to roots or stems is the selective action against phytophagous pests without toxicity to their predators. This ecological selectivity was demonstrated by Ripper<sup>1</sup>, who found that bean plants dipped in a solution of dimefox were toxic to both aphids and predators, but when dimefox was applied as a root drench, aphids were killed and predators survived.

Organophosphate materials have proved to be highly toxic to the predaceous mites *Typhlodromus fallacis* (Garman) and *Phytoseiulus persimilis* Athias-Henriot<sup>2</sup> and, in detailed toxicological studies, parathion was found to be three times more toxic to *P. persimilis* than to the prey mites, *Tetranychus urticae* Koch, at the  $LD_{50}$  level<sup>3</sup>. The use of ecological selectivity by applying root drenches of systemic acaricides seemed to be a reasonable approach to an integrated control programme for the two-spotted spider mite on cucumbers. Because several materials had been found to be effective as root drenches against the two-spotted mite<sup>4</sup>, the effect of similar treatments on *P. persimilis* was examined.

'Burpee Hybrid' cucumbers were grown in sand with a complete nutrient solution. The systemics were dissolved in 1 ml. acetone and 99 ml. water were added to give solutions 5 ml. of which were applied to the base of each small cucumber plant. After 24 h the first true leaf was excised and placed with the bottom surface up on a wet cheesecloth pad. Thirty adult female two-spotted mites and five adult female *P. persimilis* were placed on a leaf and the temperature was held at 23° C. Predator mortality was evaluated after 24 h. The toxicity of similarly treated leaves to *Tetranychus urticae* alone was determined after exposure for 48 h.

The differential effect on predators and prey is shown in Table 1.

From previous work<sup>4</sup> the  $LD_{50}$  values (in  $\mu$ g/plant) for the same type of treatment against *T. urticae* were: dimethoate 138, phorate 93, 'Temik' 154 and thionazin 106. These systemics were all of the same order of toxicity to the two-spotted mite. If there were complete ecological

selectivity, predators should not be killed by this type of treatment because they do not feed on the plants. It is obvious that there is a food-chain toxicity when predators fed on prey mites which were feeding on toxic plant juices. There were significant differences in the predator mortality caused by the various systemics and the order of decreasing toxicity was dimethoate, thionazin, phorate and 'Temik'.

The only material which consistently favoured *P. persimilis* was 'Temik'. This material is a carbamoyl oxime while the other three are phosphorothioates or phosphorodithioates. Perhaps the predator mites can metabolize 'Temik', so that it is not accumulated. The predators fed on many prey in a period of 24 h, and if they are not able to metabolize the phosphate materials there would be a "biological magnification" of the residues comparable with that found in other ecosystems<sup>5</sup>.

Thus the application of systemic acaricides to the root zone does not provide an ecological selectivity in all cases, and materials will have to be evaluated to find those that do not show a food-chain toxicity to the predators.

## Regulation of Egg Output of Populations of *Ostertagia ostertagi*

THE concentration of eggs or larvae of parasitic nematodes in the faeces of host animals has long been regarded as an indication of the number of mature parasites present. Several causes of variation in the relationship between the number of worms and the faecal egg count have been considered, among them changes in the quantity of faeces passed and in its consistency, and diurnal fluctuations in count have been much studied. Moreover, it is recognized that the ovulation of parasites in a resistant host may be inhibited.

Recent work with *O. ostertagi* in cattle has contributed to an understanding of how the egg output of populations of this parasite is regulated. Groups of calves were fed infective larvae daily at different rates with the consequence that their worm burdens were maintained at different levels. The pattern of their faecal egg counts, shown in Fig. 1, was identical, rising to the same peak and declining in the same way. The mean faecal egg counts of groups of calves, carrying different numbers of worms, were the same at any given time, and, by slaughtering calves from each group at intervals and examining their worm burdens, it was found that on each occasion the total number of ova contained in the uteri of all the worms from each calf was very similar.

In groups of calves infected with different numbers of larvae on one occasion only, the faecal egg counts were also very similar although the number of worms present was different. Calves from each group were slaughtered at intervals and it was found that the numbers of eggs contained in the uteri of all the female worms in each calf was about the same. These findings suggest that there is a limit to the number of eggs which can be produced by the population as a whole and that, except in very small populations, the worms produce eggs at a rate considerably lower than that of which they are potentially capable.

Such a limitation might occur if the production of each egg required a fixed quantity of some factor which was present in a limited amount. There is evidence, however,

Table 1. EFFECT OF SYSTEMIC ROOT DRENCHES ON TWO-SPOTTED SPIDER MITES AND THE PREDACEOUS MITE *Phytoseiulus persimilis*

Treatment	Dosage ( $\mu$ g per plant)	Mortality (%)	
		Two-spotted mite	<i>P. persimilis</i>

	200	94	30 (10)
	100	70	0 (25)
Thionazin	150	90	100 (25)
	80	89	100 (25)
	35	72	50 (16)

\* Number of predators in each test.

Fig. 1. Mean faecal egg counts of three groups of calves infected daily with 500 (●—●), 1,000 (×---×) and 1,500 (○....○) larvae, respectively, and carrying appropriately different burdens of worms.

that the immunity of the host is involved. Treatment of the host with cortisone derivatives largely eliminates the restriction of egg output and egg counts of calves given cortisone may be many times higher than those of control calves carrying a comparable number of worms (Fig. 2). The egg counts of groups of calves receiving similar cortisone treatment, but infected at different rates, were the same, which indicates that the effect of cortisone had been to raise the limit to egg production and not to stimulate the worms directly. Abnormally high egg counts may also occur in calves which appear unable to respond normally to infection and in calves clinically affected by severe ostertagiasis in which the absence of the usual signs of resistance suggests that immunity has broken down.

Faecal egg counts of calves receiving regular daily doses of infective larvae, of calves infected on one occasion only and of naturally infected calves all follow the same pattern, rising to an early peak from which they decrease logarithmically (Fig. 3). This pattern appears to be quite independent of whether the numbers of worms are increasing or decreasing. In calves infected once, egg counts begin to decline before the number of worms and although egg counts decrease logarithmically the curve of decreasing worm numbers resembles a rectangular hyperbola. It seems that the regulation of egg output is a self-contained mechanism. The logarithmic form of decrease implies

Fig. 2. Mean faecal egg counts of two groups of infected calves. ●—●, Control group; ○---○, group treated with cortisone.

Fig. 3. Faecal egg counts (on a logarithmic scale) of a group of calves which became infected on pasture.

that the egg count at any one point in time bears a constant relation to that at another point in time which precedes it by a fixed interval. This could mean that the limit to egg production depends on the experience that the host has had of the egg laying activity of the worms and not on any other aspect of the infection.

Logarithmic decreases in egg counts have been seen in infections of many species of nematodes in a great variety of hosts. When the characteristics of the egg count curve have been noted, as by Sarles<sup>1</sup>, who fitted curves of the form  $y = a(b)^{-x}$  to the egg counts of dogs infected with *Ancylostoma caninum*, it has been assumed that the curve reflects a loss of worms proceeding at a constant rate.

The finding that faecal egg counts are likely to run a stereotyped course which bears little relation to the worm burden has two important practical implications. First, within wide limits, the extent to which a pasture will be contaminated when grazed by cattle infected with *O. ostertagi* will not be influenced by how heavily the calves are infected. Secondly, no conclusions regarding the worm burdens of calves can be drawn from faecal egg counts except in two situations where these differ greatly from the expected pattern. Very low counts in the second month after first exposure to infection are likely to mean that few worms are present and high counts in calves that have been exposed to infection for some months and in which they would normally have fallen to low levels, may indicate severe helminthiasis.

## BOOK REVIEWS

### ATOMIC ENERGY AND AGRICULTURE

#### Isotopes in Plant Nutrition and Physiology

(Proceedings of a Symposium on the Use of Isotopes in Plant Nutrition and Physiology jointly organized by the IAEA and the FAO of the UN, and held in Vienna, 5-9 September 1966. Proceedings Series.) Pp. 596. (Vienna: International Atomic Energy Agency; London: H.M.S.O., 1967.) 323 schillings; 84s. 4d.; \$12.50.

THE publication of the proceedings of agricultural symposia by the International Atomic Energy Agency in association with the Food and Agriculture Organization of the United Nations has nearly become an annual event. The first meeting took place in Bombay in 1962; Brunswick and Ankara were visited in 1963 and 1965. In September 1966 a meeting on "Isotopes in Plant Nutrition and Physiology" was held in Vienna. The forty-five papers presented at that meeting are reproduced, together with the resulting discussion, in this volume.

The joint FAO/IAEA Division on atomic energy in agriculture is located in Vienna. Its objectives are not explicitly set out in this volume, but they are perhaps implied in the foreword: "Shortage of food is the world problem of our time, and there is little doubt that the adequate and correct use of fertilizers provides the most certain and rapid means of increasing food supplies. Studies such as are reported here are of great value to the proper understanding of the basic factors affecting plant nutrition and crop fertilization. For many such research problems in plant physiology and nutrition the use of isotopes has become indispensable, and the scope for isotope techniques is great." Similarly, at the beginning of the previous volume it was stated that "The early application of radioisotopes to studies of soil fertility and plant nutrition revealed new approaches and gave rise to new research procedures which are yielding valuable additional information on improved methods of crop production", and that the symposium had been arranged to discuss recent progress in this field. Thus it seems that the organizers of this enterprise wish their publications and other activities to be judged by their potential contribution towards raising the standard of agricultural production.

The reader who seeks news of such achievements is likely to turn first to the opening group of papers in this volume which are concerned with the nutrition of plants grown in soil and the concluding sections on genetic aspects of nutrition. The decision of a library committee on whether to purchase the book is also likely to be determined by the content of these sections. The remainder of the book, over half the total, is concerned with a wide range of topics in plant physiology, mostly relating to inorganic plant nutrition, though the movement of growth substances and photosynthesis receive some mention. The main link connecting these varied topics appears to be the use of tracer methods. A few of the contributions are by well known authors in Europe or the United States, whose work is familiar from scientific journals.

Representatives of the European Association for Research in Plant Breeding contributed to the discussions on genetic aspects of nutrition and F. G. H. Lupton (Cambridge) summarized lucidly the importance of this subject in plant breeding, noting important questions on which information is meagre. Among the subjects reviewed were the adaptability of species to nutritional

factors (R. G. Turner, J. Antonovics and their associates, Aberystwyth) and intervarietal differences in response especially to minor nutrients (J. C. Brown, Beltsville). Many of the contributions were of much narrower interest, attention being confined to the quantities of ions absorbed by different varieties in a single set of environmental conditions. In discussion G. G. J. Bange (Netherlands) aptly indicated the limitation of this approach; changes in environmental factors can induce similar effects on the uptake of nutrients by a single species. Unfortunately, his comments did not stimulate general discussion on the types of physiological observations which are meaningful and it is surprising that relationships between nutrient uptake and the growth and morphology of plants, especially their root systems, received so little mention. Considerable differences in the total extent and branching of root systems can occur between closely related varieties, and may markedly affect the intimacy of contact between roots and the soil. Thus the comparative study of root form would appear to be one of the most obvious starting points (though not necessarily the only one) in work on varietal differences in absorption of nutrients from the soil. The relevance of this aspect is evident from the results presented by Baker and his colleagues (Pennsylvania). Some intervarietal differences observed in field conditions were not reproduced in plants grown on a homogeneous substrate in the greenhouse; intervarietal differences in the depth of rooting were suggested but not examined. This is a field in which the "whole-plant" physiologist, interested in nutrition, could make a considerable and essential contribution.

Because of the complexity of factors which affect the availability to plants of nutrients in the soil and the consequent slow progress of research, it would be unreasonable to criticize the papers on this subject because no important new concepts were discussed. The types of tracer procedure used in most of the experiments, however, have now been used for a sufficient period for it to be reasonable—and because of the cost involved most desirable—to consider their likely long-term contribution to the solution of agricultural problems.

There is, of course, no doubt that tracer methods can be of considerable value—indeed often indispensable—in work on the physical chemistry of ions in the soil or the absorption mechanisms of plants. But the same is true of many other modern research tools, and it does not establish that special place for tracers in the armament of the research worker which symposia of the present type may suggest. This volume provides no clear evidence to refute the view that in field studies of the use of fertilizers, as opposed to basic research, conventional chemical methods may yield information of equal practical value.

The use of "labelled" fertilizers in large field experiments has been encouraged in a number of parts of the world, and so the description by Cho and his colleagues (Joint FAO/IAEA Division of Atomic Energy in Agriculture) of an experiment in the placement of ammonium sulphate as a fertilizer for maize, has topical interest. Eight methods of placement were compared but none affected the yield and nitrogen content of the crop. The use of nitrogen-15 as a tracer, however, enabled uptake from a fertilizer zone to be compared with that from the remainder of the soil and appreciable differences between different methods of placement were evident early in the season. These findings are valuable only if it is valid to assume that the pattern of uptake from different parts of the soil would have been exactly the same if the experiment had been carried out on a soil where fertilizers are beneficial. There seems to be no basis for believing this—especially when no direct evidence is provided—because gradients of nutrients can markedly affect root development and performance. Would it not be wise to limit experiments on fertilizer placement to areas where crops respond to fertilizers?

In the early stages of the evolution of a technique which demands new expertise, there may be some justification

for special arrangements to stimulate attention to the new opportunities it may provide. Once a procedure has become generally accepted and widely used, as tracers now are, such arrangements may become redundant, or even a disadvantage; they may encourage undue emphasis on one type of approach relative to others—and also inflate an already distended literature. The present volume suggests that it may now be timely to consider whether this situation has been reached in the Vienna agricultural enterprise. It would be of much interest if the Food and Agriculture Organization were to review this subject. With its wide responsibility for agricultural development throughout the world that organization is well placed to assign tracer methods to their appropriate place side by side with other modern methods for studying the field problems of agriculture. If the volume should stimulate such discussion, its publication would be most welcome.

R. SCOTT RUSSELL

## KEEPING FOOD FRESH

### Radiation Preservation of Foods

A Symposium. (Advances in Chemistry Series, No. 65.) Pp. viii + 184. (Washington, D.C.: American Chemical Society, 1967.) \$7.

ALTHOUGH attractively turned out, this volume represents a classic example of a symposium publication which might have served a useful purpose had it been available within a reasonable time after the meeting it reports (September 16–17, 1965). As it is, it is limited to work done in the United States and Great Britain, and much of the material which it contains has been superseded by the rapid publication of the proceedings of the International Symposium on Radiation Preservation of Food sponsored jointly by the FAO and the International Atomic Energy Agency, which was held in Karlsruhe in 1966 (*Proceedings of an FAO/IAEA Symposium on Food Irradiation*, Karlsruhe, 1966, STI/PUB/127, Vienna, IAEA, 1966, H.M. Stationery Office). Indeed, much of the blame for the delay in publication of the present volume can be laid squarely on the editor, as two papers by one author bear a “date received” which is one full year later than that on the remaining papers.

If papers given at specially organized symposia are to be of value, they must appear promptly, and the discussion which develops from them is often of greater importance than the papers themselves. As it does not include discussion, the present volume fails on both grounds; however, the quality of the individual papers is good. Of particular interest to me was the voluminous (but data-packed) contribution on *Radioactivity Criteria for Radiation Processing of Foods* by H. W. Koch and E. H. Eisenhower. They point out that a useful criterion for induced radioactivity is its non-measurability—by limiting the maximum energy of the radiation used to less than 10 MeV, radioactivity induced by irradiation of foodstuffs is unmeasurable. T. R. Benn, in a report on shallow irradiation of oranges to delay or prevent mould infestations, shows the technical feasibility of the process but underlines the lack of a commercial market for this process in the United States, while A. F. Novak *et al.*, in a report on the radiation pasteurization of fish and shellfish make the cogent point that radiation processing offers no panacea to replace quality control in the selection of wholesome products for preservation. Radiation processing will not improve the quality of poor food, but it will retain the attributes of good food.

In the preface to this volume, the symposium chairmen point out that in a world where more than half the human race is ill-fed, more than one-third of all food grown or raised is spoilt. The application of ionizing radiation for food preservation has great potential, but because it is not yet a commercially competitive process in the well

developed countries and is thus little used, the developing world views irradiated foods with suspicion—“if you don’t eat it, why should we?” This very real problem seems to have received little attention in the present volume, and indeed, despite the wide ranging topics of the fifteen papers it contains, this book cannot be regarded as a comprehensive view of its subject. ROGER J. BERRY

## LIFE UNDER CONTROL

### Regulation and Control in Living Systems

Edited by H. Kalmus. Pp. viii + 468. (London, New York and Sydney: John Wiley and Sons, Ltd., 1966.) 90s.

THE most characteristic feature of living organisms is their capacity to adapt themselves, by means of regulatory responses, to a wide range of different circumstances. Until a generation ago many biologists ascribed this regulatory capacity to “vital” forces, not amenable to a mechanistic analysis. This attitude has radically changed during the last two decades. The gap between “mechanistic” and “vitalistic” systems has been greatly narrowed by developments from both sides of the gap. Mechanistic systems, thanks to progress in engineering, mathematics and computer science, can closely simulate the regulatory responses of living systems, and the analysis, by the methods of biochemistry and molecular biology, of biological controls has provided an extensive understanding on the basis of the physical and chemical properties of the molecules concerned.

In this book, Dr Kalmus and twelve other experts (mostly from University College, London) survey various aspects of biological control mechanisms. The emphasis is on the conventional “biological” type of control based on hormonal rather than molecular analysis. Brown-Grant discusses extensively regulation and control in the endocrine system. Other chapters deal with the regulation of plant growth, by P. R. Bell, of animal development, by D. R. Newth, and with circadian regulation, by H. Kalmus. Three chapters review the control of populations. These are by J. B. Free, on seasonal regulations in the honey bee colony, A. D. Blest, on relationships between insects and their predators, and V. C. Wynne-Edwards, on regulation in animal societies and populations.

The molecular aspects of regulation are discussed by D. Lewis. There are also chapters on the basic mathematics of control and on control in engineering, by B. R. Wilkins, and on the early history of biological regulation, by J. S. Wilkie.

This book will be of great value to those who are interested in a broad survey of the subject.

H. A. KREBS

## MAN, TREES AND HISTORY

### Forestry in the English Landscape

By Roger Miles. Pp. 303 + 39 plates. (London: Faber and Faber, Ltd., 1967.) 105s. net

MULTIPLE land-use is a much discussed topic nowadays but implementation of planning is frequently difficult to achieve. Often forestry has a part and sometimes an important part to play in land-use because it can provide utility, amenity, recreation and sport. Roger Miles combines the professions of forester and landscape architect and in his book he traces the importance and the neglect that have been given to trees in the English landscape. This historical account is not only interesting but essential to a proper understanding of the subject because it does show the background to the present philosophy of landscape design. Evelyn’s concern at the devastation of England’s woodlands and the likelihood of a shortage of oak for the navy brought about a short-lived campaign of

planting. But it was largely due to the eighteenth and nineteenth century landowners that an English landscape was created by large-scale planning and planting of broad-leaf-trees for aesthetic and material reasons. With the industrial revolution came blocks of conifers and the rise of pressure groups which tried, without any unity, to adjust a balance between the utilitarian and the aesthetic. The next phase was dominated by war and the Forestry Commission and its modifications in policy and by lethargy and then enthusiasm in non-State forestry. Now we have arrived at the stage where multiple land-use is accepted, certainly in theory, but not yet sufficiently in practice.

Roger Miles uses his experience on Exmoor as "a contribution to the study of techniques for expanding the forest industry so that harmony between use and beauty can be assured". He shows how his system of survey, analysis and deduction can be applied to make positive recommendations and his sketches amply demonstrate his text. This book will attract the attention of those interested in the countryside whether they be professionals or amateurs. It is factual (except for a confusion between the Universities of Aberdeen and Edinburgh on page 129), well presented and bears the stamp of the unbiased expert.

C. J. TAYLOR

## DO NOT EAT

### Deadly Harvest

A Guide to Common Poisonous Plants. By John M. Kingsbury. Pp. 128. (London: George Allen and Unwin, Ltd., 1967.) 21s. net

THIS small book, intended primarily as a guide to common poisonous plants of the United States for the non-specialist, is written in clear, intelligible language. The subject matter is concerned chiefly with the higher plants but there are brief accounts of a few toxic plants belonging to other groups such as the fungi and algae.

The author defines a poisonous plant as one which contains a specific substance, often still unidentified, which produces a deleterious reaction in the body of man or animals when taken in a small or moderate amount. Plants which provoke allergic reactions such as "hay fever" and dermatitis are therefore excluded from consideration, with the exception of the very useful account of the allergic reaction caused by poison ivy (*Toxicodendron*) and a few other well known plants which are commonly, if mistakenly, regarded as poisonous by the public.

The historical background to our knowledge of poisonous plants of the United States in relation to both man and animals is well covered and interesting as is the discussion of such plants grouped according to the poisonous principles involved (for example alkaloids, glycosides, saponins and oxalates). A particularly useful part of the book is that devoted to plants which everyone should recognize as dangerous, with emphasis on common garden plants and weeds. This is followed by advice on treatment of cases of poisoning which may be summed up as "Send for the doctor, quick!"

Although primarily written for the American public there is a considerable amount of data relating to European plants commonly planted in the New World. Transatlantic visitors to the United States will undoubtedly find this book helpful especially families with young children. The majority of the plants encountered are illustrated by small sketches, but while these give a rough idea of what the species look like, I doubt if they are always sufficient to enable anyone totally unfamiliar with the flora of North America to recognize them.

Although useful as a book of reference this can also be enjoyed by being read at random. In this way one may read an account of the death of Socrates after drinking his cup of hemlock (*Conium maculatum*), learn of the gruesome symptoms of poisoning by water

hemlock or cowbane (*Cicuta virosa*) which led to the death of one poor unfortunate Jacob Maeder in 1670, or find that such familiar plants as lily-of-the-valley (*Convallaria majalis*) and wisteria are toxic. It may also come as a surprise to those who, like me, consume apples down to and including the core and pips, that the latter are decidedly poisonous. A case is cited of a man who considered apple pips such a delicacy that he saved them until he had a cup full and then ate them with fatal results. One can but hope the poison is not cumulative!

British readers should be warned that while the author refers to the plants by their popular non-scientific names, these do not always refer to the same plant so-called in this country. For example the term cowslip in the United States is used as an alternative popular name for the marsh marigold (*Caltha palustris*). An index is provided however, in which latin generic names are indicated against each popular name. One further criticism is that because this work is published in Britain it is a great pity the text was not suitably modified to include accounts of some of our more common toxic plants such as deadly nightshade (*Atropa belladonna*), henbane (*Hyoscyamus niger*), and laburnum, to name but a few.

This attractively produced little book, however, succeeds well as a guide to the common poisonous plants of the United States and the author is to be congratulated for presenting his data in both readily understandable language and an interesting manner.

DEREK A. REID

## CANCER RESEARCH GOES ON

### Methods in Cancer Research

Vol. 1. Edited by Harris Busch. Pp. xvi + 612. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1967.) 224s.

THE first volume of this series is divided into three sections, "Morphology", "Transplantation and Metastasis", and "Carcinogenesis". The ten chapters have been written by different authors. The first three chapters on electron microscopic cytology, autoradiographic methods, and karyological methods have no specific bearing on oncology and deal with methods for the analysis of normal as well as cancer cells. These chapters offer concise practical information for applying the techniques and are sufficiently detailed for the beginner. Some of the individual sections possibly are too brief, but in general adequate reference to more detailed accounts is given.

The chapter on tumour transplantation contains sections on inherited susceptibility to transplanted cancer, histocompatibility genes, actively acquired immunity and exceptions to the laws of transplantation. The section on transplantation techniques is well written and illustrated by helpful diagrams. The remainder of the chapter describes tumour-host relationships, tumour progression, metastasis, and factors affecting tumour growth.

The chapter on tumour metastasis has sufficient scope and practical detail to be of interest to a wide range of readers. The section on carcinogenesis contains chapters on epidemiology, tests for chemical carcinogens, aminoazo carcinogenesis, viral oncogenesis and the identification of viruses by electron microscopy.

Adequate testing of compounds for carcinogenic activity, for co-carcinogenic activity or for other synergistic effects has become more important as it has become more obvious that many human cancers are produced by environmental carcinogens. This comprehensive critical account is therefore timely. There are one or two statements, however, concerning the carcinogens themselves which are unjustifiably presumptive, in particular "that compounds which cause tumours at the point of application are the actual (carcinogenic) agents", because there is now considerable

evidence to implicate metabolites of the carcinogenic hydrocarbons, for example, as the proximate carcinogens. The following section in which enzyme activations are discussed is weakened by the almost total absence of literature citations.

The chapter on aminoazo carcinogenesis is heavily weighted in favour of the importance of protein binding in carcinogenesis and the section describing nucleic acid interactions is too sketchy and inadequate by comparison. A statement such as "except for a few papers, the binding of the carcinogenic aminoazo dyes to rat liver nucleic acids has not yet been confirmed" obviously requires further amplification and a list of the references the author has in mind.

The long chapter on viral oncogenesis contains a wealth of information, although the factual, sometimes uncritical manner in which the material is presented tends to make reading tedious. The final chapter describing viral identification is very technical and might have been better placed before the preceding chapter.

This volume should prove useful to those wanting to acquire a general background knowledge of cancer research and the specific techniques employed in it; it is relatively free from errors and is adequately illustrated.

G. P. WARWICK

## LOOKING DOWN

### Air Survey in Economic Development

By Rolt Hammond. Pp. viii + 246. (London: Frederick Muller, Ltd., 1967.) 45s.

It would be very difficult to guess what topics are included in this book, for the subject could be approached in a number of ways according to the author's specialist interest. In general, the book covers some aspects of photogrammetry, air photo interpretation with special reference to geology, airborne geophysics, survey aircraft and navigational aids, and a review of techniques, and examples, of selected aspects of air surveys which have been carried out. The two main defects of the book very soon become evident. The first is the way in which the material is presented; the second is in the breadth, balance and content of the material selected.

The chapter titles suggest an orderly and systematic approach which is far from evident in the text. For example, chapter four, "Cameras and Plotting Equipment", includes detailed information about colour film processing, stereoscopy, and a comparative study of colour and black and white film in a photogeology study of Hong Kong. On the other hand, there are lengthy descriptions of plotting equipment under the heading of "Air Survey Techniques" in chapter two. Nowhere is there a comprehensive review of the types of aerial photographs in current use. Information on this topic is scattered throughout the book, often in the most unsuitable places; for example, an explanation of Trimetrogon photography occurs in the middle of a section on air survey for geological purposes.

Most of the information in the book is either a summary, or a direct copy, of an article or paper. Unfortunately, the choice of material seems to have been quite random. In many instances, instead of a general review of the topic under consideration the information presented deals either with only a single, and often non-representative, example or it is a review or copy of an entire paper, much of which is quite irrelevant to the topic under consideration. This results in considerable repetition; photogeology is dealt with in three different chapters in spite of the index giving only one.

At the end of most chapters the references are listed, although there are a number of instances where papers are referred to quite extensively in the text, but which are not listed. The author's obvious lack of specialist

knowledge in the topics he deals with is evident in the apparently haphazard choice of material, much of which is not really suitable, and most of which is out of date. A typical example is the way in which he has dealt with the measurement of distance using electronic instruments. These instruments use either micro radio waves, light waves or lasers, but only one make—the 'Tellurometer'—a radio-wave instrument, is dealt with. Furthermore, the bulk of this deals with the early 10 cm wavelength models (*MRA* 1 and 2), and, except for the general discussion on the theory of measurement, most of what is written is now only of historical interest. The lengthy details of field operation and accuracy tests of these early models are of little value now that newer and more improved models are available. The whole range of light wave instruments are disposed of in a single paragraph, and lasers are not even mentioned.

The much shorter reference to a more recent model of the 'Tellurometer' range (model *MRA* 101) is taken from a paper presented at a symposium on electromagnetic distance measurement at Oxford in 1965. While the author refers to this paper, he does not indicate that it is almost a direct copy of it. Furthermore, he fails to mention some very important differences between the *MRA* 1 and 2, which he discusses fully, with this newer model. One of the main differences is that the *MRA* 101 has an entirely different method of read out—a dial which gives direct readings in metres and centimetres. No mention is made of the other 'Tellurometer' models—the *MRA* 3, and the recently developed *MRA* 4, which has a direct digital metric read out and for which is claimed an accuracy of  $\pm 3$  m.m.  $\pm 3$  p.p.m.

The first chapter, "The Scope of Air Survey", is concerned primarily with the use of aerial photographs in geological mapping, and to a lesser extent with airborne techniques in geophysical surveying. Apart from a short paragraph on the application of air survey to forestry, the vital considerations of such important topics as agriculture, hydrology, soil surveys and urban and rural land use studies are not even mentioned.

The second chapter, on air survey techniques, is particularly mixed up, and only a small part of it is concerned with the actual techniques of air survey. It contains subject matter relating to almost every other chapter in the book, much of it merely a repetition of what has been dealt with elsewhere. Two photogrammetric plotting instruments are discussed: the 'Wild A8' briefly, and the Thompson-Watts plotter in considerable detail. Many technical terms are used but not explained, so unless the reader already has some knowledge of photogrammetry most of the descriptions and comment will have little meaning. An interesting review of an example of an air survey which was carried out in 1947 by Huntings Surveys for the British Railways is discussed. This involved the production of a 1:480 plan of several miles of railway track, and is an early example of very large scale plan production using air survey methods, though nowadays the compilation of 1:500 plans with 1 ft. contours is quite a common air survey task.

The third chapter, "Instruments for Air Survey", deals with the historical evolution of gyros and the gyro-pilot, the Doppler and Decca systems of air navigation, and the Airborne Profile Recorder. The Decca system is considered at great length; the Decca Navigator Company having compiled a number of well illustrated and informative publications, including one entitled "The Decca Navigator as an Aid to Surveying".

In the fourth chapter, "Cameras and Plotting Equipment", only four out of the sixty or more air survey cameras available are dealt with, and of the plotting equipment only the 'Wild A8' is dealt with in any detail.

Unfortunately, the author has misunderstood some of the information which he has copied from the Wild

Company's pamphlet on the A8. He states that "In addition, a mobile unit has been developed which can be readily mounted, dismounted, and transported to any required site". This implies that a second type of A8 unit has been developed, whereas the pamphlet is merely pointing out the improvements in portability of the A8 over its predecessor, the A6.

Less than one quarter of the fifth chapter, "Aircraft for Survey", deals specifically with survey aircraft. Most of the chapter is concerned with two examples of survey projects in which aircraft were used. The first example is the air lift organized in the construction of the mid-Canada Line, an air detection unit, and the second, which takes up more than half the chapter, is a very general review of the work carried out by the Falklands Islands Dependencies Aerial Survey Expedition of 1955-57.

In the final chapter, "Examples of Air Survey", the author states that he refers "to some typical examples carried out in recent years". He then proceeds to review a paper, written twelve years ago, which discusses three non-typical "border line cases in which air survey was used". This is followed by a discussion on aerial survey for cadastral mapping and includes both techniques and a number of examples of work carried out. The author states, "Probably the most valuable and objective advice given to countries since the war on economic development has been contained in the reports prepared by the technical missions organized by the International Bank for Reconstruction and Development". Several references are made to these most valuable and useful reports, which deal particularly with the underdeveloped territories of the world. In almost every case they recommend the taking of aerial photographs for both map compilation, and as a source of information in the conservation and development of the natural resources. This is followed by some very useful information on photogeology taken from a paper by J. A. E. Allum. This paper is quoted as a reference though no mention is made of a very well written and informative book, *Photogeology and Regional Mapping*, by the same author. Finally, there is another review dealing with airborne geophysics in geological surveys.

Almost at the end of the book (the author's nineteenth) he reveals his reason for writing it when he comments: "The technical advances which have taken place in air survey over the past twenty years or so have received less publicity than was their due, with the result that there still exists widespread ignorance of the methods now employed in this field, and this book is an attempt to try and improve matters".

It is doubtful whether this attempt has been successful.

W. GORDON COLLINS

## FIND A WORD

### Russian-English Translators Dictionary

A Guide to Scientific and Technical Usage. By Mikhail J. Zimmerman. Pp. 294. (New York: Plenum Press, 1967.) \$12.

THIS dictionary calls itself a translators' dictionary and the translators envisaged are those working on scientific and technical texts. What is ideally demanded of such translators is a good working knowledge of the Russian language together with a working knowledge of the subject of the book or article to be translated. This, in the majority of cases, is an impossible demand. If a specialist in a subject is also fluent in Russian he is more likely to devote his time to original work than to translation. Translators, then, are usually more familiar with ordinary Russian than with the scientific or technological terms of a particular discipline. It was to help such people that Dr Zimmerman conceived and executed his book. Has he succeeded in his very laudable purpose?

His method has been to take Russian words, terms or phrases, printed in Russian and arranged alphabetically. Each is followed by one or more example in English, drawn from technological or scientific writings, in which the words which could be translated by the Russian word or phrase are in heavy print. Where desirable there are cross references. It is an ingenious idea, but one which is extremely difficult to realize in practice. The present dictionary will be far more useful to technologists than to scientists, for only a small proportion of the terms is of interest to scientists. When these terms are spread over the numerous sciences the coverage for any one science is very thin indeed.

Another criticism concerns the inclusion of a large number of everyday prepositions, adjectives and adverbs, the use of which in a scientific or technological context differs little from their use in ordinary literary Russian. About nine pages (that is eighteen columns) deal with the use of *B* (in) in various phrases. Quite a number of these are very obvious uses of the preposition in its generally accepted meaning. On page 101 seven quotations are given in connexion with the Russian word *Krome* (besides). The seventh quotation is: "There was little doubt about the good process performance of all the functional elements with the exception of the fluidized bed itself". It is difficult to see "with the exception of" as a synonym of "besides".

Examples such as these only emphasize the difficulties which beset an author who is "blazing a trail". With the ever growing volume of translations from Russian technological works, the need for a dictionary of this kind is clear and although, as Dr Zimmerman himself points out, this one is selective rather than exhaustive, it should, if used with discretion and common sense, prove a useful tool for the harassed translator.

S. I. TOMKEIEFF

## SOCIOLOGY FOR STUDENTS

### Sociology

An Introduction. Edited by Neil J. Smelser. Pp. xx+744. (New York and London: John Wiley and Sons, Inc., 1967.) 68s.

THIS volume is intended as an introductory text for students of sociology at university level. It consists of eleven chapters by well known authorities, which cover the main areas of specialization within modern sociology. There is an introduction and a concluding chapter by the editor, who has been successful in ensuring a high degree of consistency in both the matter and style of his collaborators' work. Unlike most of the other multi-author texts in the field, the book thus achieves a definite unity; the advantages of specialist contributions are not cancelled out by a lack of overall coherence. In view of this and the general quality of the writing, it is probable that during the next few years this text will become one of the most widely used on both sides of the Atlantic. For this reason it is perhaps all the more important that certain shortcomings—at least from the ideal—should be noted.

First, it must be said that despite the editor's express aim of providing an introduction to sociology on a rather higher intellectual level than is usual, the treatment of basic methodological and theoretical issues is often superficial. Many of the questions the intelligent newcomer to sociology is likely to ask about the nature of the subject as a science or discipline are not discussed in a way that will be found satisfying. Secondly, very little is said directly about the procedures through which sociological investigation is carried out. To regard this as a matter which can be left entirely to a separate text on "research techniques" now appears as somewhat old-fashioned. Thirdly, the overall view of sociology that the book presents carries a considerable American bias. Even accepting American pre-eminence in the field and the fact that the text is

intended primarily for American students, the almost total neglect of the rather divergent perspectives of much present-day European sociology is to be regretted.

JOHN H. GOLDTHORPE

## ELECTRONIC DEVICES

### Low Noise Electronics

By W. P. Jolly. (Introductory Science Texts.) Pp. vii + 149. (London: The English Universities Press, Ltd., 1967). 25s. net.

THIS is the first of a new series of introductory texts. Professor Jolly, who edits the series, and who is also the author of this book, writes in the foreword: "The books in this series are intended to be short and simply written so that they may be read in a few days by anyone with the general background of a second year student".

Although the book is called *Low Noise Electronics*, only one of the nine chapters and two of the six appendices are concerned particularly with electrical noise. Many topics have been squashed into this small book, and a superficial treatment is inevitable. The structure of the book and the selection of the material seem to have been motivated by an attempt to include references to as many modern electronic devices as possible. To devote four pages to applications of lasers (including punching a hole in a razor blade) seems to be an extreme example of seeking for topicality at the expense of neglecting the main theme of the book.

The treatment is almost entirely descriptive. When the occasional mathematical expression is given, the reader is usually referred to another book for the derivation. Throughout the text, the reader is confronted with strange new words and expressions. If he turns up the index, he will be referred back to the page on which he first saw them. For example, he meets for the first time on page 13: "elliptical orbits", "electron spin", "nuclear spin", "quantized"; on page 20: "crystal lattice", "electrons of opposite spin"; and on page 29: "effective mass", "hot electrons". Without previous knowledge of many of the terms, the reader must surely find much of the text incomprehensible. The scant illustration makes his task more difficult.

The book is well indexed, and it is possible that some busy engineers will find it useful for reference. They can, for example, turn up "Gunn effect", and be referred to original papers. Ironically, it is this all-embracing character of the book which is largely contributory to its failure to fulfil the professed aim of the author. I believe that this book falls well short of being a good introductory text.

J. G. THOMAS

## YIELD AND FRACTURE

### Physical Basis of Yield and Fracture

Conference Proceedings, Oxford, Sept. 1966. (Conference Series, No. 1). Pp. vii + 303 + 21 plates. (London: Institute of Physics and Physical Society, 1966.) 90s.

THIS volume contains collected papers on various aspects of fracture presented at a conference organized by the Stress Analysis Group of the Institute of Physics and the Physical Society. Although the meeting was originally billed as a national meeting, papers from the United States, Soviet Union, Australia and Japan were presented indicating the genuine interest in this field. During the past eight years, however, no fewer than four international conferences on this now over-exposed subject have been held (Swampscott, USA, 1959; Maple Valley, USA, 1962; Melbourne, Australia, 1963; and Sendai, Japan, 1965) all published in either book or journal form, and inevitably containing the main ideas on the subject. The Oxford

meeting comes at the end of the line of meetings and too soon after Sendai for any substantially new ideas on fracture to have been produced. As a consequence, the book turns out to be a fairly insignificant volume, but with the editorial staff working valiantly in an attempt to give good value for money by including thirty-eight papers either in full or in summary together with reported discussion.

The main papers are grouped together in four sections under the chapter headings "Theory", "Metals", "Polymers" and "Miscellaneous Materials", respectively. The first small chapter deals with certain aspects of stress distributions associated with cracks in photo-elastic materials and with the dislocation approach to fracture nucleation and propagation. The second chapter contains several papers dealing with yield and fracture in mild steel or iron-based solid solutions, some interesting observations of ductile fracture in metals containing hard second-phase particles, and an electron metallographic study of stress-corrosion cracking in austenitic steels and titanium alloys. The third and longest chapter of the volume is concerned with fracture of polymers from both the microscopical and continuum viewpoints. Particularly interesting papers include fatigue fracture behaviour in both rubber and plastics, and a fracture mechanics approach to corrosion stress cracking in plastics. The fourth chapter contains a mixed collection of papers on various ceramics such as magnesium oxide, lithium fluoride and graphite, and one, rather out of place, on cleavage surface energy experiments in zinc; no discussion was offered in response to this paper even though the surface energy values obtained were extremely low and less than reliably derived values for the stacking fault energy.

Possibly the most useful feature of this book is that several experimental and theoretical approaches can be compared for a wide range of materials. R. SMALLMAN

## LANGUAGE BY COMPUTER

### Introduction to Computational Linguistics

By David G. Hays. Pp. xvi + 231. (London: Macdonald and Co. (Publishers) Ltd., 1967.) 70s. net

IN his preface Mr Hays defines computational linguistics as "a body of techniques that make the computer an effective, workable tool for language processing"; and towards the end of his book, on the subject of automatic translation, he writes, "The problem is clearly one of engineering". Indeed it is clear throughout that when Mr Hays is faced with a new and intractable linguistic puzzle, his first reaction is to send a man out to hire a faster computer. It is not surprising then that although he devotes a whole chapter, for instance, to techniques for representing and handling grammars in a machine, he nowhere considers whether the types of grammar in question are adequate to describe the syntax of a natural language. In sum, the book is scarcely concerned at all with the linguistic side of computational linguistics, but only with the realization of the linguist's ideas in terms of tapes and disks and core store.

Moreover, it is notable that Mr Hays describes in detail virtually every aspect of the programmes with which he is concerned, with the sole exception that he neither compares their capabilities nor provides any examples of their results. Are there nowadays parsing algorithms capable of producing an output which is recognizably a sentence plus an assigned syntactic structure? Are there any examples of automatic translation fit to print? My own answers to these two questions would be "Yes" and "No" respectively, but it is curious that Mr Hays does not give any account at all of how well different systems work in practice.

Leaving aside the lack of linguistic theory, someone with a previous knowledge of computers entering the field

of computational linguistics for the first time would find this book a pleasant and useful introduction to some of the tricks of the trade. Simple accounts are given of the more straightforward parsing algorithms at present in use, of suitable techniques for establishing and maintaining large computer dictionaries, and also of such loosely related aspects of language data-processing as concordance-making and on-line indexing and abstracting. Mr Hays's RAND Corporation background occasionally obtrudes (does any other group of linguists really care, for instance, that line-printers can't usually produce italic or bold-face letters?) but on the whole, and always with the limitations already mentioned, his book is a very fair introduction to some main areas of present day work.

PAUL BRATLEY

## EARLY ASTRONOMER

John Kepler

By Angus Armitage. Pp. 194+4 plates. (London: Faber and Faber Ltd., 1966.) 21s. net

KEPLER's life and work present the most difficult problems of narrative and interpretation for a modern biographer. The work he did was strongly shaped by his personal and professional affairs, which were conducted in a provincial corner of Central Europe, then torn by religious dissension and eventually by the Thirty Years' War. Also, his personal style of work is extremely difficult for us to grasp; the intimate combination of a speculative mathematical-religious mysticism with painstaking and self-critical research is foreign to our experience of either science or "mysticism".

In this brief and elementary biography, Dr Armitage succeeds in overcoming most of these difficulties. The political and religious background to Kepler's environment is sketched in just sufficient detail to make it comprehensible; and the "neo-Platonic" aspect of Kepler's thought is presented clearly and with a minimum ofology. The technical side of his astronomical and mathematical work is popularized well, although the description of the classic study of the orbit of Mars relies rather heavily on older sources, and ignores the recent studies which exhibit Kepler's "seventy trials" of a circular orbit as an iteration procedure intended to yield approximation solution. For the assessment of Kepler's place in the history of science, the safe course is to stick to the later use of the "Three Laws" up to their re-statement in Newton's grand synthesis. This is Dr Armitage's approach. But from this we achieve no perspective on the tradition out of which Kepler's peculiar style and choice of problems rose, nor of the milieu in which his speculations were sober and moderate compared with those of such influential figures as Robert Fludd. Both of these problems have been but scantily explored by historians; but Armitage's incidental descriptions of these matters may at least inform the modern reader that they are there to be studied.

J. R. RAVETZ

## OBITUARIES

Professor H. T. H. Piaggio

June 25 there disappeared from the Nottingham scene a remarkable man who had served the University College the University of Nottingham from his appointment in 1908 until his retirement in 1950. When I first met him he was professor of mathematics and in his teaching covered the whole range of the subject to the standard of the University of London honours degree. He was 83 when he died.

Piaggio organized his life somewhat rigidly in compartments: academic activities, chess at the Mechanics Institute, and social service in connexion with his sister's work for the PDSA. At our first meeting he made it clear that he never accepted social engagements. He was unmarried and lived with his sister, a highly cultured and intelligent woman, until her death a few years ago.

On the research side he was interested in the algebra of invariants, the theory of relativity and the mathematics of psychology. But he will best be remembered for his book, *Differential Equations*, and his great teaching ability. He told me that as a young lecturer he was very disappointed with his teaching, and that while watching the antics of a cheapjack at Nottingham Goose Fair it suddenly occurred to him that the cheapjack's techniques might be applied to the serious teaching of mathematics, and accordingly he applied them with great success.

He took keen interest in the welfare of his students. Any unlikely to obtain honours in mathematics were firmly, if gently, shunted into another department; but his good students were carefully tended. Once, when an able woman student was having a poor time in her home, he asked my wife if she would arrange through a women's organization for him to pay the student's fees for residence in a hostel, without disclosing that he was involved. When she agreed, he further asked her to suggest a suitable dress allowance for the student, and this also was secretly passed on.

During the Second World War I saw much of him on the firewatching teams and learned much about him. He bitterly regretted the time which in his youth, for scholarship reasons, he had been forced to spend on the study of classics—particularly Greek—to which he attributed his defective eyesight. He followed to the end of his life a strict diet prescribed for him by a doctor in about 1910. He was very keen on chess and organized an international conference in Nottingham in 1938. But, perhaps, even more than chess or mathematical research, he enjoyed reviewing books for *Nature*, and I am sorry that we shall no longer hear his characteristic half-chuckle.

L. F. BATES

Dr. Carl Kenty

CARL KENTY, who died at his home in Cleveland Heights, Ohio, on June 10, was a research physicist with the General Electric Company for more than 30 years.

With a B.Sc. from Dalhousie and a Ph.D. from Princeton he first worked at Princeton under K. T. Compton on electron-positive ion recombination in what would now be called a decaying plasma. In 1929 he joined the General Electric Company, where his technical work was devoted to the development of gaseous discharge light sources—lamps of the "illuminated sign" type. He obtained more than fifteen patents in this field. Other more purely scientific work consisted of a series of investigations in gaseous electronics, many centred on the "active nitrogen" problem. Other investigations were a sequel to his work at Princeton, and there was also a group of experiments in which he pioneered into the medium pressure region, from the low pressure area, using inert gases, mercury, nitrogen and various metal vapours, particularly thallium. He was not content with merely recording the beautiful and complex effects observed, but used them to obtain data such as mobilities, and to search for new high-lying metastable levels of molecular nitrogen. Towards the end of his life he returned, among other work, to investigate the persistence of fine dust in plasmas.

Kenty's demonstrations of basic processes of light production were for many years a highlight of the annual conference on gaseous electronics held at various cities in the United States. He was also a fellow of the American Physical Society, past president of the Cleveland Physics Society and a member of the Ohio Academy of Sciences.

## University News:

### Alberta

PROFESSOR J. A. JACOBS, at present head of the Department of Geophysics and director of the Institute of Earth Sciences in the University of British Columbia, has been appointed Killam Memorial professor of Science.

### Hull

DR S. A. RAMSDEN has been appointed to the chair of applied physics.

### Southampton

THE Department of Education and Science and the Ministry of Health have agreed to set up a new medical school to start work early in 1971. To begin with, Southampton will take 130 medical students a year. The University Grants Committee is to be given an additional allocation of capital funds to finance the rebuilding of the Southampton General Hospital and the construction of the medical school buildings. The Government is proud to boast that annual intake to the medical schools has increased from 2,020 in 1960 to more than 2,500 last year and also that proposals for other developments in medical education will be considered after the Todd Commission on Medical Education reports early in 1968. The University of Keele has taken the unusual step of making a general statement of its willingness to set up a medical school which can begin to take students two years earlier than Southampton.

### Massachusetts Institute of Technology

MR J. F. COLLINS, at present mayor of Boston, has been appointed visiting professor of urban affairs.

## Appointments

COMMANDER JOHN O. BOYER has been appointed chief of the US Coast and Geodetic Survey's Marine Chart Division.

CAPTAIN NORMAN E. TAYLOR has been appointed director of the Pacific Marine Center of the US Coast and Geodetic Survey in Seattle, Washington, in succession to Rear-Admiral Harold J. Seaborg.

MR ROBERT W. RAMSEY, jun., has been appointed the US Atomic Energy Commission's scientific representative in Chalk River, Canada. Mr Ramsey is at present chief of the Technical Policy Branch of the Division of Operations Analysis and Forecasting at the commission's headquarters in Germantown, Maryland.

PROFESSOR A. G. WARD has been re-appointed chairman of the Food Standards Committee for a further period of three years. Mr C. S. Dence and Dr R. Passmore have been re-appointed members of the committee and Mr C. C. E. Sopp has been appointed a member, all for a period of three years.

THE following appointments have been made to the American Society of Plant Physiologists: *President*, Professor A. T. Jagendorf of Cornell University; *President-Elect*, Professor L. Bogorad of Harvard University; *Secretary*, Dr H. W. Siegelman of the Brookhaven National Laboratory.

## Announcements

PROFESSOR EUGENE I. RABINOWITCH of the University of Illinois has been awarded the 1967 Kettering Award by the American Society of Plant Physiologists in recognition of his scientific contributions on photosynthesis, and Professor Paul Kramer of Duke University is the 1967 recipient of the Barnes Life Membership Award of the society, conferred in recognition of his contributions to science through research and teaching.

THE Seismological Society of the South West Pacific is being formed in order to devote attention to the earthquakes of South East Asia, Australasia and Oceania. Further information can be obtained from the Convener Seismological Society of the S-W Pacific, Box 8005 Wellington, New Zealand.

THE John A. Hartford Foundation, Inc., of New York City, has awarded \$268,000 to the Massachusetts Institute of Technology for a three-year programme to continue development and evaluation, prepare manufacturer's drawings and specifications and build twenty production models of a high-speed English to Braille embossing system, being studied at MIT. This machine would enable an ordinary typist with no knowledge of the raised dot Braille code to produce immediate Grade 2 Braille the most widely used form of the touch system of reading for the blind.

## Meetings

LECTURES on Radioisotope Work in School, September 4-15, Harwell (Post-Graduate Education Centre, Building 445, AERE, Harwell, Didcot, Berks.).

LECTURES in Engineering, September 11-15, Harwell (Post-Graduate Education Centre, Building 455, AERE Harwell, Didcot, Berks.).

COLLAGEN Discussion Group, September 25, University of Manchester (Professor D. S. Jackson, Department of Medical Biochemistry, Burlington Street, Manchester 13).

EXPERIMENTAL Medicine and Surgery in Primate, September 27-30, New York City (Executive Director: The New York Academy of Sciences, 2 East 63 Street, New York, NY).

GONDWANA Stratigraphy, September 26-October 1, Buenos Aires (Dr E. P. Plumstead, Honorary Secretary, Subcommission on Gondwana Stratigraphy, Bernard Price Institute for Paleontological Research, University of Witwatersrand, Johannesburg).

CREATING Scientists and Technologists for Industry, September 28, Imperial College (The Secretary, The Research and Development Society, 51 The Mall, Ealing, London, W5).

BUSINESS Decision 67, September 28-29, University Southampton (Conference Information, The British Computer Society, 23 Dorset Square, London, NW1).

METAL Ions in Biological Systems, September 28-29, Inorganic Chemistry Laboratory, Oxford (Dr H. A. Hill, Inorganic Chemistry Laboratory, South Parks Road, Oxford).

INFRA-RED Spectra of Gas Chromatographic Fractions, September 29, University of Technology, Loughborough (Miss J. Healey, Institute of Petroleum, 61 New Cavendish Street, London, W1).

ERRATUM. In Table 1 of the article "Free Amino-acids in Blood Plasma and Erythrocytes of Normal Ducks and Ducks infected with Malarial Parasite, *Plasmodium lophurae*" by Wasim Ahmad Siddiqui and William Traub (Nature, 214, 1046; 1967) the value for cystine for erythrocytes (parasitized, 80 per cent) should have been 2.0, 50.0.

ERRATUM. In the leading article "Molecular Mode" (Nature, 215, 802; 1967) the name Hodgkin was, of course misspelt and should have been Hodgson.

CORRIGENDUM. In the communication "Concentration of Immunglobulins in Lethally X-irradiated Mice" (Nature, 215, 742; 1967) the names H. Bazin and H. S. Mick were unfortunately printed in the wrong order.

## FORTHCOMING EVENTS

Meetings marked with an asterisk are open to the public

Wednesday, August 30—Wednesday, September 6

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE (at Leeds)—29th Annual Meeting.

Wednesday, August 30

At 7.30 p.m.—Lord Jackson of Burnley, F.R.S.: "Science, Technology and Society" (Presidential Address).

Thursday, August 31

At 10 a.m.—Prof. C. E. H. Bawn, F.R.S.: "Horizons for Plastics" (Presidential Address, Section B).

At 10 a.m.—Dr. R. F. Parrington, F.R.S.: "The Origins of Mammals" (Presidential Address, Section D).

At 10 a.m.—Prof. A. R. Prest: "Sense and Nonsense in Budgetary Policy" (Presidential Address, Section F).

At 10 a.m.—Dr. R. Week: "Co-operative Research in a Competitive Industry" (Presidential Address, Section G).

At 10 a.m.—Miss Freda Gwilliam: "New Ventures in Education" (Presidential Address, Section L).

At 10 a.m.—Mr. F. R. Horne, C.B.E.: "The Potentiality of Plants for Improving Food Supplies" (Presidential Address, Section M).

At 10 a.m.—Dr. J. Needham, F.R.S.: "The Roles of Europe and China in the Evolution of Occumenical Science" (Presidential Address, Section X).

At 11.15 a.m.—Prof. E. A. Shils: "The Profession of Science" (Presidential Address, Section N).

At 11.30 a.m.—Prof. M. B. Wilkins: "Biological Clocks" (Darwin Lecture).

At 2.30 p.m.—Prof. E. R. Laithwaite: "Propulsion Without Wheels" (Young People's Lecture).

Friday, September 1

At 10 a.m.—Prof. R. F. Peel: "Geomorphology—Trends and Problems" (Presidential Address, Section E).

At 10 a.m.—Dr. R. D. Keynes, F.R.S.: "The Predetermination of Sex" (Presidential Address, Section I).

At 10 a.m.—Mr. T. A. Oxley: "A Scientific Policy for the Better Use of Food" (Presidential Address, Section K\*).

At 11.20 a.m.—Dr. M. J. Henchman: "What Happens During a Collision When Two Molecules Collide and React" (Kelvin Lecture).

At 2.30 p.m.—Dr. B. D. Shaw: "Explosives" (Young People's Lecture).

At 8 p.m.—Dr. B. J. Mason, F.R.S.: "Weather Forecasting by Computer" (Evening Discourse).

Friday, September 3

At 10.30 a.m.—Official Service in Leeds Parish Church. Preacher: The Most Reverend and Right Honourable F. D. Coggan, P.C., D.D., Lord Archbishop of York.

Friday, September 4

At 10 a.m.—Dame Kathleen Lonsdale, F.R.S.: "Physics and Ageing" (Presidential Address, Section A).

At 10 a.m.—Mr. N. L. Falcon, F.R.S.: "The Geology of the North-East Margin of the Arabian Shield" (Presidential Address, Section C).

At 10 a.m.—Dr. A. T. Lucas: "Felling and Napping in Early Ireland" (Presidential Address, Section H).

At 11.30 a.m.—Dr. D. E. Broadbent: "Aspects of Human Decision Making" (Presidential Address, Section J).

At 11.30 a.m.—Prof. T. A. Bennet-Clark, C.B.E., F.R.S.: "The Role of the Senses in the Modern World" (Presidential Address, Section K).

At 2.30 p.m.—Dr. B. J. Mason, F.R.S.: "Thunderstorms and Lightning" (Young People's Lecture).

At 8 p.m.—Mr. D. R. Pilbeam: "Human Origins" (Evening Discourse).

Saturday, September 5

At 11.30 a.m.—Dr. J. A. Gray: "The Physiological Basis of Personality" (Young People's Lecture).

At 2.30 p.m.—Prof. C. S. Whewell: "The World of Fibres" (Young People's Lecture).

## APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

SCIENTIFIC OFFICER or SENIOR SCIENTIFIC OFFICER (with a first- or upper second-class honours degree in botany, agricultural botany or agriculture, and at least three years' postgraduate experience) in the SYSTEMS SYNTHESIS SECTION of the DEPARTMENT of ECOLOGY, to work on theoretical aspects of plant and crop growth—The Secretary, Grassland Research Institute, Hurley, Maidenhead, Berkshire (August 31).

ASSISTANT LECTURER (preferably wishing to develop an interest in either bacterial microbiology, electron microscopy, microbial genetics, or protozoology) in MICROBIOLOGY in the DEPARTMENT of BIOLOGICAL SCIENCES, to assist in the teaching of students preparing for the B.Sc. Honours Degree in Microbiology, and to participate in the research work of the Department—Academic Registrar (LFG), University of Surrey, Battersea Park Road, London, S.W.11 (September 4).

LECTURER (with some experience of diagnostic morbid anatomy and of histopathology to medical undergraduates) in the DEPARTMENT of ANATOMY—The Secretary, The University, Aberdeen, Scotland (September 6).

LECTURERS (2) (registered medical practitioners, preferably with some experience of medical bacteriology) in the DEPARTMENT of BACTERIOLOGY—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (September 8).

ASSISTANT LIBRARIAN (graduate)—The Secretary, The University, Dundee, Scotland (September 9).

ASSISTANT LECTURER in ORAL ANATOMY and PHYSIOLOGY—The Registrar, The University of Sheffield, Sheffield (September 9).

TECHNICAL OFFICER (graduate, or equivalent, with some experience in crystallography or electro-mechanical equipment) in the DEPARTMENT of CHEMISTRY to assist with the use of automatic X-ray crystal diffractometers—The Secretary, The University, Dundee, Scotland (September 9).

LECTURER (registered medical or science graduate preferably with previous teaching experience) in ANATOMY—The Registrar, University College, Cathays Park, Cardiff (September 11).

ASSISTANT LECTURER or LECTURER in PHARMACOLOGY in the DEPARTMENT of PHARMACY—The Registrar, The University, Nottingham (September 15).

JUNIOR RESEARCH FELLOW (with a good honours degree in physics and research interests in solid state physics) in PHYSICS—The Registrar, The University of Sheffield, Sheffield (September 15).

LECTURER or ASSISTANT LECTURER (registered member of the veterinary profession) in VETERINARY PATHOLOGY, for duties which will include the teaching of morbid anatomy and histopathology—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (September 16).

LECTURER (with a medical qualification) in the DEPARTMENT of ANATOMY—The Registrar, The University, Liverpool, quoting Ref. RV/142/N (September 16).

LECTURER or ASSISTANT LECTURER (qualified in an appropriate science or in medicine) in PHARMACOLOGY—The Registrar and Secretary, The University, Leeds, 2 (September 18).

RADIOGRAPHER/TECHNOLOGIST in the DEPARTMENT of RADIATION BIOLOGY and RADIOTHERAPY, College of Medicine of the University of Lagos—The Inter-University Council, 33 Bedford Place, London, W.C.1 (September 20).

SENIOR TUTOR-DEMONSTRATOR in GEOGRAPHY at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 22).

POSTDOCTORAL FELLOW in ORGANIC CHEMISTRY to join a group working on the chemistry of ortho-quinones—Professor J. M. Tedder, Chemistry Department, The University, Dundee, Scotland (September 23).

LECTURER (with at least a Ph.D. or equivalent, and preferably some teaching experience in biochemistry) in the SCHOOL of BIOCHEMISTRY, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 30).

BASIC GRADE SCIENCE GRADUATE (with some basic knowledge and interest in human physiology) for research into the oxygen-binding properties of red-blood cells—Dr. T. L. Dormandy, Whittington Hospital, Highgate Hill, London, N.19.

BOTANIST/PLANT PHYSIOLOGIST (with a good honours degree, sound experience in physiological and biochemical techniques, and adequate research achievement) for studies on the biological changes accompanying maturation and senescence of fruit under selected storage regimes, with particular reference to the physiological disorders arising during long storage and to the application of the results of basic research—The Secretary, East Malling Research Station, Maidstone, Kent.

LECTURER in CIVIL ENGINEERING; a LECTURER in GEOLOGY; and LECTURERS (2) in ZOOLOGY at University College, Nairobi, University of East Africa—The Inter-University Council, 33 Bedford Place, London, W.C.1.

LECTURER in AGRICULTURAL BIOCHEMISTRY—Grade III; and an ASSISTANT ADVISORY NUTRITION CHEMIST—Grade IV (applicants should possess an honours degree in biochemistry, agricultural chemistry or equivalent)—The Secretary, The Edinburgh School of Agriculture, West Mains Road, Edinburgh, 9.

MASTER to teach PHYSICS; and a MASTER to teach MATHEMATICS—The Headmaster, Whitgift School, Haling Park, South Croydon, CR2 6YT.

MICROANALYST to take charge of the MICROANALYTICAL LABORATORY—The Laboratory Superintendent, Chemical Laboratory, The University of Sussex, Falmer, Brighton, Sussex, quoting Ref. 940/2.

RESEARCH ASSISTANT in the EXPERIMENTAL PSYCHOLOGY LABORATORY for a research project on long- and short-term memory—The Assistant Registrar (Establishment), The University of Sussex, Essex House, Falmer, Brighton, Sussex, quoting Ref. 937/1.

RESEARCH STUDENTS in CHEMISTRY for work in the following fields: solid state chemistry; "hot atom" chemistry; nuclear chemistry—The Registrar, The University, Canterbury, Kent, quoting Ref. A71.

SCIENCE GRADUATE or SENIOR TECHNICIAN for specialized work on blood groups and electrophoresis of haemoglobin, serum proteins and enzymes—The Director, Serological Population Genetics Laboratory, c/o St. Bartholomew's Hospital, West Smithfield, London, E.C.1.

SENIOR LECTURER in the SCHOOL of MATERIALS SCIENCE—The Registrar (S), The University, Bath, Somerset, quoting Ref. 67/93.

SENIOR MATHEMATICS MASTER (graduate with experience) at Markham College, Lima, Peru—The Appointments Branch, The British Council, 65 Davies Street, London, W.1, quoting Ref. 7/WS 298.

TECHNICIAN (at least 21 years of age, preferably with City and Guilds or I.S.T. qualifications) to assist in the teaching and research laboratories of the CHEMISTRY DEPARTMENT—The Staff Officer, University of Surrey, Battersea Park Road, London, S.W.11.

## REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

## Great Britain and Ireland

Proceedings of the Royal Society. Series A: Mathematical and Physical Sciences. Vol. 299, No. 1456 (13 June 1967): A Discussion on Nonlinear Theory of Wave Propagation in Dispersive Systems. Organized by M. J. Lighthill. Pp. 145+1 plate. (London: The Royal Society, 1967.) 22s. 6d.; \$3.35. [47]

Ministry of Agriculture, Fisheries and Food. Bulletin No. 136: Watercress Growing. Pp. iv+35+4 plates. (London: H.M. Stationery Office, 1967.) 4s. 6d. net. [47]

The British Steel Castings Research Association. 14th Annual Report, 1967. Pp. 42. (Sheffield: The British Steel Castings Research Association, 1967.) [47]

## HOW TO BUY NATURE

Volumes start in January, April, July and October, but subscriptions may begin with any issue.  
The direct postal price per subscription for one or two copies of NATURE each week is:

### \*12 MONTHS (52 issues and 4 indexes)

Great Britain and Eire..... £14.0.0 each  
United States of America..... (by air freight)..... \$44 each  
Canada..... (by air freight)..... \$47.80 each  
Elsewhere overseas by surface mail..... £13.15.0 each

(Charge for delivery by air mail on application)

\*Shorter periods *pro rata*. (Minimum three months.)

### MULTIPLE SUBSCRIPTIONS

For subscribers who take more than two copies of NATURE each week these reduced annual rates are offered:

### 12 MONTHS (52 issues and 4 indexes)

Number of Copies	G.B. & Eire	U.S.A.	Canada (by air freight)	Elsewhere (surface mail)
3-5	Each £13.10.0	Each \$42	Each \$46.00	Each £13.10.0
6-11	£12.15.0	\$40	\$43.60	£12.15.0
12 or more	£12.0.0	\$38	\$41.70	£12.0.0

Multiple subscriptions must run concurrently. Every copy will be posted separately, and for speed of delivery each subscription can be addressed to a different individual, or department at the same address. (ZIP essential for U.S.A.)

TRADE MARK

## Silicones *from* Esco (Rubber) Ltd

SILICONE  
**GREASE SG2000**

For laboratory and engineering use for temperatures from  $-50^{\circ}\text{C}$  to  $+200^{\circ}\text{C}$ .

SILICONE  
**FLUIDS SF4000**

Various viscosities for many applications.  
50 lb. and 450 lb. drums only.

SILICONE RUBBER  
**MOULDING PASTE  
SR300**

Cold setting for easy making own elastic mouldings without catalyst, for temperatures from  $-50^{\circ}\text{C}$  to  $+200^{\circ}\text{C}$ .  
Tubes approx. 100 gr. 24/- each.

SILICONE RUBBER  
**MOULDING PASTE  
SR600**

Cold setting easily pourable for making elastic mouldings with catalyst, for temperatures from  $-50^{\circ}\text{C}$  to  $+200^{\circ}\text{C}$ .  
1 lb. tins 42/9 each.

SILICONE RUBBER  
**TRANSLUCENT  
TUBING**

3 grades, over 30 standard sizes from 0.5 mm i.d., elastic, excellent resistance to many chemicals, used extensively for peristaltic pumps, surgical applications, transfer of food, electrical insulation, etc. at temperatures up to  $180/200^{\circ}\text{C}$ .

SILICONE RUBBER  
**TUBING SR70**

Elastic electrical grade for temperatures up to  $300^{\circ}\text{C}$ .

FLUOROSILICONE RUBBER  
**TUBING F.S.R.**

Elastic, with excellent resistance to many solvents, for temperatures up to  $200^{\circ}\text{C}$ .

SILICONE RUBBER AND  
FLUOROSILICONE RUBBER  
**MOULDINGS**

Sheets in a wide range of thicknesses, discs, laboratory and industrial bungs in over 100 sizes and other mouldings.

SILICONE RUBBER AND  
FLUOROSILICONE RUBBER  
**MOULDING  
COMPOUNDS**

Several grades available for export to some countries for manufacturers of silicone rubber products.

**Esco (Rubber) Ltd** Walsingham House, 35 Seething Lane, London EC3

## Hematoquick

Need a rugged, dependable micro-hematocrit centrifuge that delivers up to 15,000 rpm for efficient running of micro-capillary blood cell volume testing? We've got it: our Model MB Hematoquick. □ It also gives you: An automatic start/stop timer. Constant speed. An electric brake for 15-second head stops. Quiet, cool-running performance. Your choice

of three capillary heads, one micro chemistry head, and two types of readers. □ What's

the payoff? Three-minute hematocrits. (We told you it was a Hematoquick.) □ Write for Bulletin MB. And see how fast we send you our hematocritique.

**INTERNATIONAL  
EQUIPMENT CO.**

300 SECOND AVENUE • NEEDHAM HEIGHTS, MASSACHUSETTS 02194

**Classified Advertisements**

Semi-displayed £4 16s. per single column inch. Minimum £2, each additional 1/12th of an inch 8s. Full page £132. Half page across £66. Colour (orange) £15 extra. 1s. is charged for the re-direction of replies to advertisements with a box number.

ADVERTISEMENTS SHOULD BE ADDRESSED TO: T. G. Scott and Son, Limited, 1 Clements Inn, Strand, London, W.C.2. Telephone: 01-405 4743. Telegrams: Textualist, London, W.C.2.

**APPOINTMENTS VACANT****NEW ZEALAND**

Wellington Hospital Medical Unit

J. R. MCKENZIE RESEARCH FELLOW  
IN BIOCHEMISTRY

**Interesting position for  
BIOCHEMIST**

Suitably qualified Science Graduate required for position as Biochemist to Wellington Hospital Medical Unit, undertaking clinical research in lipid field and major epidemiological cardiovascular surveys among Polynesians in Pacific and New Zealand in 1968-69. Return fare United Kingdom for appointee and family after three years' service. Preference for Ph.D. or M.Sc. with experience in lipid carbohydrate metabolic field, a sense of adventure, and a desire to visit Pacific Islands. Commencing salary within scale NZ\$3,350 to NZ\$4,730.

For conditions of appointment apply Professor W. J. H. Butterfield, Department of Medicine, Guy's Hospital, London, S.E.1. (626)

**UNIVERSITY OF EDINBURGH****DEPARTMENT OF VETERINARY  
PATHOLOGY—LECTURER OR  
ASSISTANT LECTURER**

Applications are invited from registered members of the Veterinary Profession for the post of Lecturer or Assistant Lecturer in Veterinary Pathology. The duties will include the teaching of morbid anatomy and histopathology, and there are good facilities for research. Previous experience in pathology will be an advantage but the post offers good training for the recent graduate wishing to study this subject. Salary Scales, Lecturer, £1,470 to £2,630 per annum; Assistant Lecturer, £1,105 to £1,340 per annum, with placement according to qualifications and experience, and with superannuation benefit.

The successful candidate will be expected to take up duty on November 1, 1967, or as soon thereafter as possible.

Further particulars may be obtained from The Secretary to the University, University of Edinburgh, Old College, South Bridge, Edinburgh, with whom applications (six copies), giving the names of two referees, should be lodged not later than September 16, 1967. (644)

**PHYSICISTS**

Urgently sought for a variety of important projects with experience in the following fields—Optics, lasers, Ultrasonics/Infrared systems or instrument design—Theoreticians working with experimentalists in radiation, propagation/scattering, pattern recognition or solid state.—A. Cecil Harper, M.A., G.K. Bureau Ltd., 196 Oxford Street, W.1. 01-636 6858. (X581)

Leading Swiss Chemical Firm requires

**AGRONOMIST FOR INDONESIA****Qualifications :**

Degree in entomology  
Experience with insecticides and in experimental techniques.

**Responsibilities :**

Evaluating insecticides in Sumatra.  
Supervision of trials of demonstrations in rice.  
Promotional activities for insecticides.

Applicants should send their handwritten *curriculum vitae* together with references to

Box No. 931, *Nature*, T. G. Scott & Son Ltd., 1 Clements Inn, London, W.C.2.

Employees of the firm are aware that this position is being advertised.

(X585)

**AUSTRALIAN NATIONAL  
UNIVERSITY****INSTITUTE OF ADVANCED STUDIES  
RESEARCH SCHOOL OF BIOLOGICAL  
SCIENCES**

Following the recent appointment of Dr. R. O. Slayter, F.A.A., as Professor of Biology in the Research School of Biological Sciences, a Research Group is being established in the general area of Environmental Biology. The main research theme of the Group will be concerned with the effect of environmental factors on the physiological performance and ecological distribution of species and populations of special interest.

Within this theme, it is envisaged that particular attention will be given to the effects of environmental stress, especially water stress, and to the biological problems of arid, and other extreme environments.

In order to develop the Group, it is now desired to make appointments of scientists interested in this general area of research, preferably with backgrounds in one of the following fields—(i) Applied mathematics, with special reference to the mathematical study and simulation of biological processes. (ii) Environmental physics, with special reference to transfer processes in the soil and atmospheric micro-environment. (iii) Environmental physiology, with special reference to organism-environment interactions. (iv) Biophysics, with special reference to ion, water and energy exchange phenomena in cells and tissues.

Appointees will be expected to exercise a high degree of personal initiative in the development of their research activities, and will be encouraged to collaborate freely with other scientists, within and outside the Group.

Appointments can be made in the following categories: Professorial Fellow, \$A11,050; Senior Fellow, \$A8,750 to \$A10,274; Fellow, \$A6,400 to \$A8,740; Senior Research Fellow, \$A7,800 to \$A9,324; Research Fellow, \$A5,400 to \$A7,250.

Professorial Fellows and Senior Fellows are entitled to one year's study leave in every six years' service, and a Fellow one year in every seven years' service, on full pay. A contribution towards travel and other expenses on study leave is paid.

Professorial Fellows are appointed to retiring age, Senior Fellows and Fellows are appointed for an initial period of five years; thereafter they may be re-appointed until retiring age. Senior Research Fellows and Research Fellows are usually appointed for three years, which can later be extended to five years.

All appointments carry superannuation on the F.S.S.U. pattern with supplementary benefits, reasonable travel expenses (both ways for temporary posts) and assistance with housing.

Further details should be obtained from the Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1. Applications close in Australia and London on September 29, 1967. (697)

GRADUATE CHEMIST with an Honours degree is required for research work on wood preservation. Research Laboratories are in a country district at Frome, Somerset.—Apply Personnel Manager, Cuprinol Limited, Adderwell, Frome, Somerset. (662)

**UNIVERSITY OF ALBERTA  
EDMONTON, ALBERTA, CANADA  
DEPARTMENT OF PHARMACOLOGY**

Applications are invited for the post of Assistant Professor or Associate Professor in the Department of Pharmacology from persons interested in Cardiovascular Pharmacology or Biochemical Pharmacology. The salary scale attached to this position is \$9,000 to \$12,450 for an Assistant Professor or \$12,500 to \$16,550 for an Associate Professor. The commencing salary will depend on the qualifications and experience of the successful applicant.

Further particulars of the position and of the concomitant amenities such as travelling expenses on first appointment and pension scheme may be obtained from Professor G. B. Frank, Department of Pharmacology. (513)

**UNITED OXFORD HOSPITALS**

MEDICAL PHYSICS TECHNICIAN required for Hospital Laboratory using varied instrumentation for gas analysis and medical electronics. Previous experience in Medical Laboratory not necessary. Preference will be given to applicants with training in vacuum technology and electronic instrumentation. Duties include supervision of lay staff and assisting graduates. Qualifications: H.N.C., H.N.D. or Science Degree in Applied Physics or equivalent subjects. Salary scale: £1,293 to £1,591 per annum (Technician Grade II).

Apply in writing to: Anaesthetics Laboratory, Radcliffe Infirmary, Oxford. (621)

**UNIVERSITY COLLEGE  
CARDIFF****DEPARTMENT OF ANATOMY**

Applications are invited from registered Medical or Science Graduates, male or female, for the post of LECTURER IN ANATOMY. The appointment carries responsibility for teaching preclinical medical students at ordinary and honours levels. Previous teaching experience is an advantage. The appointee must engage in research work and candidates with strong investigative inclinations will be favourably considered. Duties to commence October 2, 1967, when the department will be accommodated in new premises with comprehensive research facilities. Salary will be within the scale £1,470 to £2,730.

Applications (eight copies), together with the names of three referees, should be received by the Registrar, University College, Cathays Park, Cardiff (from whom further particulars may be obtained) not later than September 11, 1967. (603)

**DEPARTMENT OF PHYSIOLOGY  
UNIVERSITY OF OTTAWA  
FACULTY OF MEDICINE  
OTTAWA, CANADA**

Physiologist or Biochemist with physiological interest, M.D. and/or Ph.D., Assistant Professor. Applicants should be capable of independent research and of supervising graduate students. Salary according to experience, pension plan, hospital and life insurance.

Applications and inquiries should be addressed to Professor M. Beznak. (661)

# opportunities in agriculture overseas

General agriculturists and agricultural specialists of many kinds are frequently required in the effort to match the large demand from the developing countries. The vacancies advertised below are a selection from the many openings which exist now. While they are being filled, other vacancies are arising.

Salaries within the ranges quoted are assessed on qualifications and experience; and the terms of most appointments include free or subsidised accommodation, education grants, family passages, good leave on full pay, etc.

Most appointments are limited to nationals of the United Kingdom or the Republic of Ireland who are normally resident in those countries.

## BOTSWANA

### Pasture Agronomist

RC 213/19/02

Duties: To carry out, control and advise on a programme of range management investigations at two existing pasture research stations in different ecological zones; and to carry out ecological and vegetation surveys as part of a programme of assessing the natural resources of Botswana.

Qualifications and terms: A degree in Agriculture, preferably with experience of pasture research in arid areas. Salary £1,284-£2,556 a year plus a non-taxable gratuity of 25%. Two-three year contract.

## THE GAMBIA

### Agricultural Officer

RC 213/68/02

Duties: To carry out general extension work, including particularly oil palm nursery and plantation practices, to supervise mixed farming centres and to administer and supervise main Agricultural Station. Limited touring.

Qualifications and terms: A degree in agriculture with experience in general extension and mixed farming. Salary £1,140-£2,224 a year plus 25% terminal gratuity. 18-24 months contract.

## KENYA

### Adviser on Farm Management

RC 213/95/01

Duties: To conduct studies and to advise the Agricultural Development Corporation on the most economical systems of farming, and also to advise farmers connected with the Corporation.

Qualifications and terms: A degree in Agricultural Economics with experience in farm management studies, surveys and techniques. Salary range £2,500 to £3,000 a year subject to British income tax plus a variable tax-free overseas allowance currently payable at rates from £270 to £915 a year depending on marital status. Two year contract.

## TANZANIA

### Agricultural Officers (Animal Husbandry)

RC 213/173/025

Duties: To study the distribution of livestock breeds and to advise farmers on the improvement of animal husbandry.

Qualifications and terms: A university degree, with animal husbandry as a major subject, and an aptitude for work involving animal production and nutrition. A knowledge of the distribution and feeding values of different grasses; and an ability to speak Swahili is desirable. Salary £1,329-£2,757 a year plus 25% terminal gratuity. 21-27 month contract.

A contributory pension scheme is available in certain circumstances.

## Entomologist

RC 213/173/023

Duties: To be in charge of the entomological section of a regional research centre, to study the distribution of and damage done by field insect pests and to advise on their control.

Qualifications and terms: A university degree in natural science with entomology as a major subject. Post graduate training leading to a higher qualification is desirable. Salary £1,329-£2,757 a year plus 25% gratuity. 21-27 months contract.

## UGANDA

### Principal/Senior Research Officer

RC 213/183/05

Duties: To take charge of a small section of scientists investigating the breeding and selection of food crops.

Qualifications and terms: Candidates must have at least a second class honours degree in Botany or Agricultural Botany with post graduate training in plant breeding, and overseas experience. Basic salary from £1,839 to £2,175 a year, liable to Uganda income tax. In addition an allowance, normally tax-free, ranging from £888 to £936 a year will be paid by the British Government on behalf of the Uganda Government direct to an officer's bank account in Uganda. 25% terminal gratuity. Contract 21-27 months in the first instance.

## Agronomist

RC 213/183/01

Duties: To carry out an experimental programme on tea with the object of improving production methods and quality.

Qualifications and terms: A second class honours degree in Agriculture with at least three years additional experience of tropical agriculture, preferably specializing in tea. Basic salary from £798-£1,791, liable to Uganda income tax. In addition an allowance, normally tax-free, ranging from £636 to £888 a year will be paid by the British Government on behalf of the Uganda Government direct to an officer's bank account in Uganda. 25% terminal gratuity. Contract 2 years.

## ZAMBIA

### Lecturers (Grade I and II) in Agricultural Economics

RC 213/132/011

Duties: To lecture in basic and applied economics to two year diploma students taking agriculture and allied subjects, and possibly to take part in extra-mural activities. The Grade I lecturer will be responsible for the distribution of duties in the Agricultural Economics Section.

Qualifications and terms: A degree in economics or agricultural economics. A knowledge of co-operatives and agricultural marketing is desirable. For the Grade I post graduate teaching experience is essential. Salary Grade I—£1,930 to £2,275 a year plus 25% gratuity. Grade II—£1,645 to £1,955 a year plus 25% gratuity. A supplement of from £200 to £250 a year is also payable direct to an officer's home bank account. Both the supplement and gratuity are normally tax-free. 3 year contract.

For further particulars of these vacancies and an application form please write giving your full name, age and brief details of professional qualifications and experience, and quoting appropriate reference number, to the Appointments Officer, Room 324 N/8

**MINISTRY OF OVERSEAS DEVELOPMENT**

Eland House, Stag Place, London SW1.

## CSIRO PHYSICIST

### AUSTRALIA DIVISION OF CHEMICAL PHYSICS

**GENERAL.** The Division of Chemical Physics is a component of the Organization's Chemical Research Laboratories and is located in new laboratory premises adjacent to Monash University at Clayton, Melbourne, Victoria. The Division has facilities for research in the fields of optical spectroscopy; mass spectroscopy; electron diffraction and electron microscopy; X-ray diffraction; solid state chemistry, including NMR and ESR investigations; and theoretical chemistry. In addition the Division has well-equipped instrument laboratories for the design and construction of mechanical, optical and electronic equipment.

**DUTIES.** A Physicist is required for the mass spectroscopy group to conduct research, initially into the development of high efficiency ion sources, and to study the ion optics of mass analysing devices (magnetic, monopole, or quadrupole).

The research interests of this group lie in the study of the energy levels of molecular ions, of the fragmentation of molecules by electron or photon bombardment, the use of mass spectra in the identification of organic molecules and elucidation of their structure, in the development of ion sources and ultraviolet light sources, and in the application of mass spectrometers to chemical problems.

The group has three magnetic deflection spectrometers, one used for electron impact work, one coupled to an ultraviolet monochromator for photon impact work, one coupled to a vapour-phase chromatograph for organic chemical identification, and is pursuing an active programme in the development of monopole and quadrupole mass spectrometers.

**QUALIFICATIONS.** Applicants should possess a Ph.D. degree, preferably in Physics, although a chemist with physical experience would be acceptable, or have had postgraduate research experience of equivalent standard and duration supported by satisfactory evidence of research ability.

**SALARY.** Depending upon qualifications and experience, the appointment will be made within the ranges of Research Scientist \$A5,250–\$A6,622 p.a., or Senior Research Scientist \$A6,892–\$A7,974 p.a. Salary rates for women are \$A428 p.a. less than the corresponding rates for men. Promotion within CSIRO to a higher classification is determined by merit.

**CONDITIONS.** Fares paid for the appointee and his dependent family. Further particulars supplied on application.

Applications, quoting reference number 582/6 and stating full name, place, date and year of birth, nationality, marital status, present employment, details of qualifications and experience, together with the names of not more than four persons acquainted with the applicant's academic and professional standing, should reach:

Chief Scientific Liaison Officer,  
Australian Scientific Liaison Office,  
Africa House, Kingsway,  
London, W.C.2.

by the 30th September, 1967.

(685)

## GRADUATE IN AGRICULTURE OR SCIENCE

Required by An Foras Taluntais (The Agricultural Institute) for a challenging post on the development of analytical methods on feed-stuffs and biological materials in the Animal Sciences Division. Salary up to £2,465 depending on qualifications and experience. Marriage and children's allowances. Superannuation scheme including special arrangement for F.S.S.U. member. **ESSENTIAL:** Honours University degree in Agriculture or Science (majoring in Chemistry, Biochemistry or Agricultural Chemistry.) **DESIRABLE:** Experience of analytical work and staff supervision.

Application forms from The Director, An Foras Taluntais, 33 Merrion Road, Ballsbridge, Dublin 4. Latest date for receipt of application forms September 25, 1967. (658)

## UNIVERSITY OF MANCHESTER

### MANCHESTER, 13 DEPARTMENT OF PHYSICS

A Research Assistant required to run a PDP7 computer connected on line to nuclear physics experiments on a 6 MeV Van de Graaff generator. Successful candidate should have research experience in nuclear physics. Knowledge of computer programming desirable, but not essential. He will be expected to initiate and develop programmes for the on-line handling of data, and to participate in the research programme of the group. Initial salary according to qualifications and experience in the range: £1,470 to £1,830 per annum.

Particulars and application forms (returnable by September 23) from the Registrar. (667)

## AGRICULTURAL RESEARCH COUNCIL

Assistant Experimental Officer required for research on the muscular activity of large and small animals. The work will utilize a wide range of physiological and biochemical techniques, for which a basic training in Zoology or General Biology is desirable with some Chemistry.

The post exists at the new Meat Research Institute due to be completed at Langford, nr. Bristol in October/November. Basic qualifications: Pass degree, H.N.C. or equivalent in appropriate subject for candidates aged 22 or over, under 22 years—G.C.E. in five subjects, to include two 'A' level scientific subjects and English language. Salary: according to age on A.E.O. scale: £803 at age 22, £1,017 at age 26 or over; rising to £1,243, with promotion prospects. Optional contributory pension scheme: five-day week.

Application forms: Meat Research Institute, Low Temperature Research Station, Downing Street, Cambridge, quoting BP 9. (704)

## UNIVERSITY OF NOTTINGHAM

### DEPARTMENT OF PHARMACY

Applications are invited for an ASSISTANT LECTURESHIP or LECTURESHIP IN PHARMACOGNOSY. The appointee will be required to participate in teaching undergraduate students in Pharmacognosy up to Honours degree level and to participate in the supervision of post-graduate work. The appointment will be effective from January 1, 1968 and the salary will be within the range £1,105 to £1,340 (Assistant Lecturer) or £1,470 to £2,630 (Lecturer).

Further particulars and forms of application, returnable not later than September 15, from the Registrar. (671)

## UNIVERSITY OF EDINBURGH

### DEPARTMENT OF GENETICS

**POST DOCTORAL RESEARCH WORKER** required to work in association with Dr. R. A. Beatty on problems of animal gamete genetics. Current problems include the study of the genetics, immuno-genetics and physical and chemical variation of spermatozoa. Initial appointment will be for a period of two years. Salary comparable with University Lecturer's Scale.

Applications, by letter, giving the names of two referees, should be lodged with the Secretary to the University, University of Edinburgh, Old College, South Bridge, Edinburgh, 8. (655)

## UNIVERSITY OF LEEDS

### RESEARCH ASSISTANTS IN AGRICULTURAL CHEMISTRY

Applications are invited for appointment as Research Assistant in the Agricultural Chemistry section of the School of Agricultural Sciences at a salary of £825 by £50 to £925 a year. Appointment will be initially for one year and renewable up to a maximum of three years.

There are two appointments available. One is for research into the effect of the plane of energy and protein nutrition on the yield and composition of milk in the sow. The second is for research into the effect of food additives on food utilization and growth in sheep and calves. Persons appointed may be able to register for a higher degree.

Applications (three copies) stating age, qualifications and experience and naming three referees, should reach The Registrar and Secretary, The University, Leeds 2, (from whom further particulars may be obtained) not later than September 4, 1967. (664)

## SPECIAL LIBRARIAN

The rapidly growing Library of the CENTRAL ELECTRICITY RESEARCH LABORATORIES, Leatherhead, Surrey, covers a wide range of subjects including chemistry and biology, physics, metallurgy, electrical, mechanical and civil engineering. Some 450 technical and scientific journals are currently taken.

The Librarian will be responsible for maintaining close liaison with National and other Special libraries. In addition, he will be responsible for the efficient administration of the Library, the ordering, cataloguing, and classification using U.D.C.

Applicants must be professional librarians with experience in a scientific or technical library.

Salary within the range £1,555 to £1,845 per annum.

Applications, stating full relevant details and present salary to the Personnel Officer, Central Electricity Research Laboratories, Cleve Road, Leatherhead, Surrey, by September 6, 1967. Quote Ref. N/303. (680)

## BRIGHTON EDUCATION COMMITTEE

### BRIGHTON COLLEGE OF TECHNOLOGY

Required as soon as possible:

- SENIOR LECTURERS in (a) BUILDING PROCESSES AND ADMINISTRATION
- (b) MATERIALS AND ENVIRONMENTAL SCIENCE

Honours graduates, with research, industrial and/or teaching experience, to teach at all levels of Honours degree courses required. Salary (under review) £2,140 to £2,380 per annum. Increments within the scales allowed for approved experience.

Further particulars and application forms, returnable by September 4, 1967, from Registrar, Brighton College of Technology, MOULSE-COOMB, Brighton 7. (675)

## MERRY-GO-ROUND

THE changes in the composition of the British Government made public on August 28 are unlikely to have much direct effect on the interests of science and technology in the months ahead. On the whole, the gains seem nicely balanced by the losses. The most worrying change is the departure of Mr Anthony Crosland from the Department of Education and Science and his replacement by Mr Patrick Gordon Walker, if only because it introduces the biggest uncertainty in the new pattern. Since he went to the Department of Education and Science nearly three years ago, Mr Crosland has won for himself a reputation which engendered something akin to a sense of security among those associated with the department. Almost the only blot on his copybook—but a big one—is the pigheaded decision that university fees would be increased (by a factor of roughly three) for students from overseas. By way of compensation, Mr Crosland seems to have put up a stalwart fight in the past few months to prevent too great an erosion of the educational budget for the financial year ahead, and everybody will be grateful to him for that. He has been an able minister, and his friends will not be the only ones who will be disappointed that he is only being moved sideways, to the Board of Trade, and not upwards to the Department of Economic Affairs. (If Mr Crosland should choose to reconsider his predecessor's decision to build an airfield at Stansted, that will be an uncovenanted benefit of enormous value.)

Mr Gordon Walker is by comparison an unknown quantity. He is scholarly (which should help), donnish (which is if anything a disadvantage), and has such a reputation for loyalty to the Government as a whole that people will naturally fear that he will compromise too readily with other departments. To say this does not imply that compromise is necessarily bad, but merely that in the two years ahead there are bound to be great pressures on the management of resources for expenditure on research in the universities, and that the most reasonable courses of action will not necessarily be the best. The issue of whether the responsibilities of Mr Gordon Walker's department should be transferred to the Ministry of Technology is an obvious snare. There is some logic in it, and obviously there is a great and continuing need of better liaison between the two departments, yet any change in this direction should be vigorously resisted until the Ministry of Technology has shown that it would be able sympathetically to absorb university research without giving in to the temptation to spend the money on something else.

The loss occasioned by the departure of Mr Crosland will to some extent be cancelled out by the simultaneous departure of Mr. Goronwy Roberts, who has for several months been concerned with the admini-

stration of the research councils. He has not always inspired confidence on scientific matters. He will be succeeded either by Mrs Shirley Williams or by Miss Alice Bacon, either of whom would be a distinct improvement. Mrs Williams would be a particular asset. She is, after all, the best candidate in sight for the somewhat distant goal of the first woman to be Prime Minister.

For the rest, the reconstruction of the British Government may raise important issues by the changes it will bring about in the balance of power between the economic ministries and the Ministry of Technology. For several months now, and for the best of reasons, the edges between the Ministry of Technology and the Department of Economic Affairs have been confused. Both ministries, for example, are concerned with the economic health of large sections of British industry, the Ministry of Technology by its terms of reference and the Department of Economic Affairs through the working parties which are studying, with varying degrees of success, the functioning of particular sectors of industry—the "little Neddies" as some wag has christened them. Then both ministries claim credit for devising the Industrial Reconstruction Corporation, and the Ministry of Technology has moved steadily, in the three years of its existence, towards the view that the solution to a great many industrial problems is to be found in economics and not in technology in the old-fashioned sense. Yet there are tensions between the ministries as well as common purposes. Should the Ministry of Technology continue to support expensive developments such as the Concord supersonic aircraft, for example? The DEA is likely often to disagree with what the Ministry has to say. In the days when Mr Michael Stewart was in charge at the DEA, the Ministry of Technology may have had its own way too easily. Whether that state of affairs will continue now that Mr Harold Wilson has decided to take charge of the DEA himself will depend on how much time the Prime Minister can spare for paying attention to the details of his new department's work. His mere presence there, however, could create a more productive relationship between the two departments. With luck, that could be a benefit.

## WHAT IS SCIENCE POLICY?

LORD JACKSON has done a public service in his presidential address to the British Association (see page 1023) by drawing attention to the underlying complexity of what people are usually pleased to call science policy. For several years now, but particularly since the governments of several countries have been seek-

ing ways of keeping the growth—and the cost—of science and technology within what seem to be reasonable bounds, there has been a danger that many essential issues would be grossly over-simplified. For example, there has been a tendency for governments to judge the success of their policies entirely by the size of the fraction of the Gross National Product being spent on research and development. Thus in Britain, it has frequently been held that there is no great need to change the scale of support for science and technology because the magic ratio is not very much greater in the United States. In France, by contrast, where the cost of research and development was a mere 1.7 per cent of the GNP three years ago, comparisons with the United States were one of the principal reasons why the French Government embarked deliberately on a programme to increase the amount of money being spent on science and technology. The danger is that, in their preoccupation with these and other yardsticks, those responsible for public administration will overlook the more enduring criteria for deciding what to do and how much to spend.

There is already some evidence in Britain of unhealthy tendencies in directions like these. Lord Jackson has quite properly raised the question of how people should determine the sums of money to be spent on the support of fundamental research, chiefly through the research councils, and this is very much a field in which rules of thumb have recently become fashionable. Recent history is a sufficient explanation of why the administrators are rushing to embrace convenient but possibly misleading yardsticks. Between them the research councils and the University Grants Committee are now spending the best part of £100 million on the support of basic research, two-thirds of it in the universities. Expenditure under these headings has been growing more quickly than most other forms of public expenditure—by 13 per cent or so in the first half of this decade. It did not take long for people to point out that things could not go on like that. In two decades or so, pure research would be costing as much as the National Health Service—that is how the argument used to go. By the end of the century, scientific research would be consuming the resources of the whole of manufacturing industry. So it was concluded that there must at some stage be a break in the growth curve. And why not sooner rather than later? For is this not a time when Britain should be spending more on technology (which makes money) and not basic science (which consumes it)? By these and other arguments, it seems to have been agreed that there should now be a deliberate slackening in the pace of growth of spending on science. The trouble is that there is no way of knowing whether this decision is of the kind that would have done justice to Solomon or whether, on the other hand, it is just a guess.

The objective, of course, is that decisions about the amounts of money to be spent on university research should ideally be made in the light of a hard-headed appreciation of what university research is for. This is where the numbers are not much help. There is no

way of escaping the question of why university teachers should be allowed, even encouraged, to devote much of their time to activities which are not strictly pedagogical. Lord Jackson is right in saying that it is not good enough to say that research is always inestimably valuable because nobody can predict what benefits may emerge from it. That is a counsel of unreason.

The real defence of university research must ultimately lie in the old dogma that research and teaching are inseparable. If there is anything at all in that assertion, the rapid growth of expenditure on university research in the early sixties is not nearly as outrageous as it sometimes seems to the administrators. The numbers of people teaching science at the universities increased by roughly 9 per cent a year between 1961 and 1965. Is it not reasonable that the expenditure on academic research should have increased by something like 13 per cent a year, especially when account is taken of the inevitable increases of costs from one year to another—the sophistication factor as it is called—now reckoned to account for a steady increase of 4 per cent a year? And what is to happen now that there are polytechnics as well as universities providing higher education?

Two important conclusions emerge from this. First, the question is not how much the country can afford to spend on academic research, but how much it can afford to spend on higher education. Second, if the policy makers really want to make the best use of public money—as they should—it would be prudent of them to carry out a sensitive field study of the relationship between teaching and research at universities so as to devise meaningful yardsticks for deciding what costs are reasonable.

Similar pitfalls attend the making of policy for the support of industrial research. Here, too, the simpler numbers spell success. Lord Jackson points out, with all due pleasure, that industrial organizations now spend about two-thirds of all the money allocated in Britain to research and development, and that only a third of what they have to spend comes from contracts for defence research. That picture is much more cheerful than it used to be even five years ago. But how much of what is being spent is valuable? What, in any case, should be the objectives of industrial research and development? Should the policy makers have it in mind that industrial research is a kind of investment and should they seek to distinguish between successful projects and the failures by calculating some kind of economic return on every investment? By that test it seems fairly clear that many popular technological causes, the Concord supersonic aircraft among them, would be counted not triumphs but a waste of money and, what is more important, a misinvestment of men as well. In other words, in technology much more than in basic science, the sum of money being spent may be a measure of how many people are occupied on research and development but may say nothing at all about the effectiveness with which they are deployed.

But if the Government and its committees cannot

take decisions on matters like these, who is to take the risk? Luckily, the experience of the two straitened years just past has helped the British Government to a more realistic appreciation of events than had previously been possible. For one thing, it now seems to be acknowledged that industrial research and development is not really an end in itself, but one of several means by which economic prosperity may be attained, or at least sought.

From this, alas, it follows that decisions about the scale on which research and development should be supported must be made, in the last resort, by people able to calculate the potential rewards and to take the risk of deciding whether to embark on something new. For the most part, the policy makers can only cheer from the sidelines, providing encouragement and some basic help—decent information services and reproducible standards, for example. In the long run, if they really want to encourage the greater use of research and development in industry, they must find some way of helping enterprises of all kinds to take adventurous decisions. In this context, of course, it does not matter whether an industrial enterprise is nationalized or privately owned—what matters is merely that assessments about the potential value of research and development should rest with the people responsible for day-to-day survival. This is the strongest argument for asking that the Ministry of Technology should now practise what Professor Blackett has been preaching, and take effective steps to channel the talents of the public laboratories into industry.

But what if industry chooses to spend more on research and development than the existing stock of trained men and women can successfully carry out? This is a reasonable anxiety, if only because it is but a decade since Britain was acutely short of people. In this sense, it is entirely right that Lord Jackson should have devoted much of his attention to manpower. In the late sixties, however, the old problems have been transformed if not quite melted away. There is now a good deal of slack in the system. Of the 211,000 scientists and engineers at work in Britain in 1965, for example, only 40,000 or so seem to have been employed on industrial research and development. It is hard to think that industry would suddenly run short of people to carry out development if companies collectively decided to increase the scale of their research and development by, say, 50 per cent. It is true that there would be some difficulties, and that companies would have to pay their technical people less meanly, but that is a secondary consideration. It is also true that the men recruited into industry would usually leave some other field of activity bereft, for, even though the system may now be fairly flexible, there is on balance a shortage of trained people. Yet there is also a greater capacity within the system for responding to the changing pressure of demand.

In other words, manpower has almost ceased to be a cause of anxiety in its own right. Instead, it is a field in which the policy makers should be ready to seize the opportunities which may offer themselves.

It is, in particular, a crying need that something more real than lip service should be paid to the principle that the modern world needs an educational system qualitatively different from that which the Victorians invented. The most urgent need is to arrange that all of those who leave schools should know what science and technology are about, that those who leave universities trained as scientists should also know who Keynes was—and Samuelson as well—and that nobody should be required at some over-tender age to declare himself for science, medicine or the humanities without much chance of going back. If there is anything which can be dignified as science policy, it should be the province of men whose real aim is a thorough revolution of the educational system.

In this and a host of other ways, the pursuit of objectives in science policy ends up in fields as different from each other as education and the management of the economy. That is entirely as it should be, for science is no longer a separable part of a nation's activity. It follows, however, that attempts to talk about science policy in isolation from other kinds of policies run the risk of seeming nonsense. But it is also plain that the proper management of scientific resources—a term which is almost entirely synonymous with people—requires that decisions should be made on a small scale and not usually at the centre. Certainly where the fuller exploitation of technology is concerned, the Government must act remotely; there will be trouble if it intervenes too directly on its own accord. In the field of science and technology as a whole, the Government can do much to encourage a more efficient use of facilities for research. Lord Jackson was right to emphasize that in the last resort, a sensible appreciation by the public at large of what science and technology can provide is the only guarantee of good sense. He could well have added that it is equally important that there should be a general appreciation of how science and technology are not almost magical entities in their own right, but, rather, integral parts of national activities of all kinds.

How is the British Government performing by these tests? That is the question which Lord Jackson raised but did not answer. It is fair, however, to acknowledge that in the past two years a great deal has been done to create some useful machinery by means of which sound decisions can be reached. Bodies like the Council for Scientific Policy are working well. It remains to be seen how effectively the Central Advisory Council on Science and Technology will function, but there is at least a chance that good works will be done. Yet it is also plain that the contexts within which these otherwise admirable bodies function are often far too circumscribed. The Council for Scientific Policy, which has a good record for tackling general questions such as the need of computers in universities and the relationship between universities and government laboratories, has nevertheless fought shy of attempts to influence the quality of teaching in the schools and universities. That may be easier after the Dainton Committee has reported (whenever

that may be), yet there is no reason why this central issue should not have been tackled long ago. And there remain, of course, outstanding the thorny questions of the scale and the manner in which public funds should be used to support research. In other words, there has been some progress in the past three years and some of it is valuable, but there is a danger that the British Government and its committees will interpret the term science policy too literally, and thus attempt to make too many decisions at the centre. What Lord Jackson has been saying may help to push things in the other direction.

## ONE STEP ON

THE announcement in Geneva a week ago that the Russian and United States Governments have been able to put forward a draft treaty intended to limit the proliferation of nuclear weapons is a hopeful if small step forward. The Disarmament Committee has been in session at Geneva for so long now that its credibility is much in danger of erosion. If it now becomes the forum for a realistic debate on the extent to which an agreement on the proliferation of nuclear weapons can be successfully controlled by international inspection or by some other means, much will have been done to restore its reputation—and the hopes of those outside the conference that some progress on disarmament may eventually be possible.

That said, however, it is inevitable that the weeks ahead will not be comfortable for the delegations represented at Geneva. After several months of private talks, the United States and the Soviet Union have been forced to admit failure in their attempts to win agreement behind the scenes for the incorporation of safeguards provisions in the treaty they have tabled. It is no surprise that things have turned out that way (see *Nature*, **214**, 753; 1967). The United States has plainly failed to win the agreement of the member nations of Euratom that responsibility for inspection and control should be placed with the International Atomic Energy Authority at Vienna, and the Soviet Union is entirely justified in its insistence that it would be improper to delegate this task to Euratom itself.

But this, of course, is only skirmishing. The difficulties ahead are much more serious. The outstanding uncertainty is whether the nations which are not nuclear powers, and which have no intention of making nuclear weapons for themselves, will stomach a treaty which permanently confirms the nuclear powers in their present grandeur and throws the rest of the world open to international inspection designed to stifle imitative ambitions. The nuclear powers have hitherto been unreasonably hopeful of what the smaller nations would be happy to accept. For all the cheerfulness which has accompanied the tabling of the treaty at Geneva, it remains unlikely that the nuclear powers will be able to win agreement from the smaller nations without making substantial concessions on their own

account. But there are technical as well as political problems still to be resolved. How feasible will it be to design cast-iron inspection systems? How soon could a safeguards system operate? In any case, what value is there in a treaty for the non-proliferation of nuclear explosives which does not include China and France as signatories?

In the circumstances it would be entirely sensible if the nations now negotiating at Geneva were to go back almost to the beginning of the discussions about the non-proliferation treaty. To begin with, some years ago, people seemed entirely happy with the notion that a non-proliferation treaty should not include a rigid safeguards system, at least at the beginning. Only when bellicose noises from West Germany had made the Russians take fright, a year or so ago, did the issue of safeguards become a central issue and a stumbling block. But things have changed a great deal in the past twelve months. European nations have clearly become much less concerned about the advantages or otherwise of manufacturing nuclear explosives for themselves. So may it not be prudent to think now of a non-proliferation treaty in which the attempt to design a safeguards system is replaced by something less ponderous? This would be something well worth trying for. One possible line of compromise would be an international agreement that all nations would make an honest public declaration at regular intervals of all activities connected with the exploitation of nuclear materials. Nuclear powers, for example, would be required every so often to say how much uranium they had converted into a fissile form, and how much of this they had committed to the manufacture of explosives. By itself, this would do a lot to salve the injured pride of smaller nations. But there is good reason to expect that such a system, operated by the non-nuclear powers and the rest, would be a good assurance that the manufacture of nuclear explosives would not spread. After all, in the climate of mutual curiosity that would be certain to follow the signing of a non-proliferation treaty, it is extremely improbable that a nation forced to make public declarations of its activities in potentially important fields would be able successfully to keep secret the clandestine manufacture of nuclear explosives. At the same time, there would be good cause to hope that a treaty drawn on comparatively flexible lines like these would serve much more effectively than the cumbersome instrument now being negotiated as a platform from which further forays into disarmament might be attempted. Certainly it would be a great misfortune if there were so much bickering about safeguards in the months ahead at Geneva that the members of the Disarmament Committee would be persuaded to give up once more the hope of signing a treaty to bring the production of nuclear explosives by the nuclear powers under some kind of control. In other words, compromising on a system less rigid than the safeguards now in prospect would be not merely an immediate benefit but an insurance for the future. Will the negotiators seize this opportunity?

## NEWS AND VIEWS

### Aluminium at Home

SEVERAL aluminium companies have made independent proposals to the British Government about the construction of an aluminium smelting plant in Britain. Last year, 259,000 tons of unwrought and 80,000 tons of wrought aluminium were imported at a cost of more than £65 million, while the home production of aluminium ingots was only 35,000 tons. The government is doubtless aware of the savings to be made by setting up smelting works; the problem is one of cheap and adequate power supplies for these hungry users of electricity. The small Scottish plants, running on hydro-electricity and which produce most of the British aluminium, were built well before the last war. The sudden renewal of interest in the possibilities of smelting in Britain derives partly from the fear of import duty on ingots if Britain is to enter the European Economic Community and partly from the prospects of cheaper fuel.

Most of the companies are more interested in the cheapness of the electricity for their projected plants than in its source. Rio Tinto Zinc Corporation, however, has submitted a plan whereby its aluminium plant would share the entire output of a nuclear power station with the Atomic Energy Authority's gaseous diffusion plant at Capenhurst. This is at present supplied with enormous quantities of electricity by the national grid. There may indeed be logic in making large and constant users of electricity independent of the public supply, though less than 10 per cent of the electricity produced in Britain last year was generated outside the public electricity boards. The cost of the plan, both to the aluminium company and, through the effect on the national grid, to the ordinary consumer, is at present being studied by the government. There have been suggestions that the government may be able to participate in these ventures by means of a bill, soon to be introduced in the House of Commons, that would enable it to take up shares in private industry. In any case, there is always the Industrial Reconstruction Corporation. The implications of the proposals are many, and a statement from the government, when it comes, may affect a good deal more than just the aluminium industry.

### Engineering at Cambridge

At the recommendation of the Faculty Board of Engineering, the Mechanical Sciences Tripos at Cambridge is to be replaced by an Engineering Tripos. Courses for this new tripos will begin in 1968 and the first examination for Part One will be in 1970 and for Part Two in 1971. The importance of this change

lies in the fact that Part One of the new tripos will take only two years and will not be considered sufficient for a degree. All engineering students will be required to take Part Two. This change brings the engineering faculty into line with the others at Cambridge which have one by one decided to insist on a Part Two. The existing Mechanical Sciences Tripos is now the only one that still considers Part One to be a three year degree course. At present, exceptional students have been completing Part One in only two years and then going on to take Part Two, which in many ways is the equivalent of a postgraduate course.

One of the important effects of the change is that the new Part One courses will be less specialized—it must, or should, be impossible to teach in two years what previously took three. This in turn should make it easier for students to move between faculties, from natural sciences or mathematics to engineering for example, and, after all, this sort of flexibility is supposed to be a great virtue of the Cambridge Tripos system.

The new Part Two will offer a much greater variety of courses. The new tripos includes several more general courses including economics, statistics, operation research, sociology and psychology. The faculty hopes to cater not only for the outstanding engineer who wants nothing else, but also for the numerous students who would benefit from a more general outlook on how engineering fits into society and the economy. At present large numbers of engineering graduates go directly into management rather than spending some time in design, and for them the general courses now being offered are virtually vocational training.

Another change is that the results of the examination for Part Two of the new engineering tripos, like those of all other faculties, will be classified. At present Part Two of the Mechanical Sciences Tripos is a pass or fail affair. This decision to give classes is not universally welcome. There is a strong case for arguing, especially in such a broad field as engineering, that it leads to the very antithesis of education, with too much emphasis on subjects likely to turn up in examination papers rather than those that really interest the students, and, of course, supervisions becoming coaching periods. All in all, however, the new engineering tripos should prove to be a distinct improvement on the one it replaces.

### Drugs in Britain

WHEN the Dangerous Drugs Bill becomes law, two important changes will be made in the treatment of drug addicts in Britain. All addicts will have to be registered and drugs such as morphine and heroin will not be available except through special centres. The Ministry of Health has announced that there are shortly to be ten such centres for in-patients in London and thirteen centres, less closely associated with hospitals, for out-patients. Both types will cater only for heroin and morphine addicts, whose number is estimated at between 1,250 and 2,000, mostly in London. The measure was prompted by the conclusion of the Brain Committee that a few doctors were prescribing too many drugs to registered addicts, and thus supplying a black market.

The World Health Organization has now published a report on Services for the Prevention and Treatment

of Dependence on Alcohol and Other Drugs which recommends a method of treating addiction that differs in many respects from that which will be established in Britain. Rather than restrict the capacity to treat addicts to a small number of centres, the WHO committee considers that "treatment of high quality should be made available through an adequate variety of facilities to all who suffer from alcohol or drug dependence . . . The general practitioner can also be involved in treatment and rehabilitation." The WHO committee puts a great deal of emphasis on the problems of psychological and social rehabilitation. But it is difficult to see how an effective "network of facilities" concerned with helping the addict back into society can be maintained in Britain if addicts are required to register with the Ministry of Health and to move from their family doctors to impersonal clinics half way across a city. Some doctors and social workers doubt whether this kind of discipline will appeal to the drug addict, but even if the majority of addicts do attend the centres, very little attention seems to have been paid to psychological rather than physiological cure.

How far addicts can or should be compelled to undertake cures is a vexed question. Dr M. M. Glatt, the only British member of the WHO committee, endorses the view that compulsory treatment of addicts is often successful and should certainly be given to criminal addicts. He points out that it is sanguine to hope that many drug addicts would come for treatment voluntarily. On the other hand, at the homes run by the Simon Community, addicts are allowed to continue to take drugs until they may decide to be cured. The director of the Community, describing the bill as a panic measure, said that it is absurd to isolate "hard drug" addicts by subjecting them to a unique treatment. What is needed is an understanding of the "addict personality", which will become impossible if addicts are caused to reject authority further.

At this stage there is no way of knowing whether the bill will succeed in its main aim, the restriction of the supply of drugs, or whether by stimulating a black market it will make the association between addiction and crime closer still. In any case, the bill is certainly something of a makeshift: no specific sum has been allocated to the new centres and no training programme for the doctors working in them has been instituted, despite the recommendation of the WHO committee that specialists of this kind should undergo extensive training. If doctors are not trained, as Dr Glatt points out, there is a danger that the out-patient clinics will degenerate into drug dispensaries.

It is also difficult to appreciate the need to change the whole system of treatment of drug addicts in Britain in order to curb the irresponsible activities of those few doctors who prescribe excessive doses of drugs. The Swedish Drug Addiction Control Committee, faced with the same problem, has proposed that a computer record should be kept of all prescriptions. Doctors who supplied the black market could then be disciplined immediately, and the system would also prevent addicts from going from doctor to doctor in search of drugs. Could not the British Government have introduced legislation to deal with irresponsible doctors separately, and then have paid close attention to the far more serious questions of discouraging drug addiction and curing addicts both in body and mind?

## BA President

THE Council of the British Association has announced that Sir Peter Medawar will be the President of the British Association for the Advancement of Science for 1968-69 in succession to Dame Kathleen Lonsdale. Sir Peter has been the Director of the National Institute for Medical Research since 1962. He was educated at Marlborough, and Magdalen College, Oxford. While at Oxford he won the Christopher Welch Scholarship in Zoology, and became a Fellow of Magdalen by examination in 1938. He remained at Magdalen as Fellow and University Demonstrator until 1944, when he took up a fellowship at St John's College. In 1946 he returned for a year to Magdalen before becoming Mason Professor of Zoology at Birmingham University.

In 1951 he was appointed to the Jodrell Chair of Zoology and Comparative Anatomy at University College, London. It was his researches here that won him the Royal Medal of the Royal Society, of which he became a Fellow in 1949, and, in 1960, the Nobel Prize for Medicine. This latter award he received jointly with Sir MacFarlane Burnet, Director of the Walter and Eliza Hall Institute for Medical Research, Melbourne. Burnet had predicted that if an animal was exposed to an antigen at an early enough stage in development, "immunological tolerance" to that antigen would result. Medawar proved this by injecting spleen cells into newborn mice; skin grafts made on the mice showed that the mouse was tolerant of what would normally be a foreign body.

Sir Peter gave the Croonian Lecture of the Royal Society in 1958 and the BBC Reith Lectures in 1959. Before assuming the direction of the National Institute for Medical Research, he had been a member of the Agricultural Research Council and of the University Grants Committee. He is a foreign member of the New York Academy of Science and the US National Academy of Science. He was knighted in 1965.

## Tribology Catches On

IN March 1966 a committee of the Department of Education published a report on "Tribology", which is the name it coined for the science of lubrication. The committee estimated that £500 million is being wasted each year by industry through lack of knowledge of the problems of lubrication in the design of machinery, and recommended the setting up of institutes of tribology to provide a "specialist tribological service to industry". The project was widely criticized: there seemed little point in setting up grandiose and specialized institutions when the need was to spread an awareness of the problems of lubrication through industry. Even so, Britain is to get its first Centre of Tribology, according to the Ministry of Technology. The site will be announced in September.

A more immediate effect of the committee's report was to stimulate interest in lubrication science at universities and colleges. Imperial College, which last year began one week courses in lubrication, was one of the first institutions off the mark. The lecturers came from industrial companies particularly concerned with lubricants and bearings; their students have been designer draughtsmen, production engineers and technical representatives, as well as more senior staff. So diverse were the problems, from the lubrication of zoom lenses to tin dredgers, that the Department of Mechanical Engineering has decided to introduce four specialized courses into its programme for next year. These will deal with the problems of lubrication in steadily loaded, and reciprocating bearings, in car, train, ship and aircraft machinery and in machinery working in hostile environments. The courses, which are open to thirty-two people at a time, are too short for experimental work. Demonstrations do, however, follow the lectures, and the department has a flourishing mortuary of failed ball bearings. There will be two courses next term, five at Easter and three the following summer. The cost is twenty-five guineas.

Bradford College of Technology also began courses in lubrication after the committee issued its report. The college at present offers two sets of courses, one as an optional part of the examination for mechanical engineering technicians. The other is intended for semi-skilled workers, and lasts for three weeks. The college is planning to introduce a third course, to make designers and managers aware of the problems of lubrication.

The forthcoming journal *Tribology* (Hiffe Science and Technology Publications) will fulfil the most valuable of the functions of the proposed institutes, that of disseminating knowledge without arrogating a special importance to tribology. And not even the most ardent well-wishers of the new science can be altogether happy at what it has been christened. For *tribos* means "rub off", not "rub". Not "friction", but "deletion".

## Television on Tape

ICI Ltd, Ciba Ltd of Switzerland and the Columbia Broadcasting System of America have announced the formation of a partnership to manufacture and market in Great Britain and Europe a new audio-visual system known as Electronic Video Recording and Reproduction, EVR for short, which has been described as a

momentous technological achievement and an entirely new medium of communication likely to cause a revolution in the educational use of television. It is claimed that EVR will be the long playing record of television. Indeed the research and development that has led to it was done under the direction of Dr P. C. Goldmark of CBS, who earlier developed the long playing record.

The outstanding feature of EVR is that it allows for the first time the showing of pre-recorded programmes on conventional television sets. Pre-recorded film in small cassettes, only seven inches in diameter and half an inch wide, is placed in a reproduction unit, a player, which in turn is linked up to a commercial television set. Each cassette has enough film for an hour long programme in black-and-white and half an hour in colour. Furthermore, each frame can be held on the screen, and this flexibility is one of the great classroom advantages of the EVR system. A teacher can stop a programme at any time to emphasize a point.

Perhaps the most notable technological advance of the entire EVR system is the film used for pre-recording. It was developed by CBS and Ilford Ltd, a jointly owned subsidiary of ICI and Ciba, to overcome the two major problems of miniaturization, namely, the difficulty of projecting sufficient light through a very small frame to give a readable image on a viewing screen, and preventing the seemingly inevitable flickering and shakiness that occur when small frames are quickly passed through a projector. Their success in solving the problems can be judged from the fact that the film, unperforated and 8.75 mm wide, in each seven-inch cassette contains no fewer than 180,000 frames, and when projected it moves at the rate of five inches a second.

There seem to be endless possibilities for the EVR system. At present there are 20,000 television sets in English schools, not to mention the universities and technical colleges, and these could be much more efficiently used if teachers were freed from the restrictions of national programmes. Moreover, EVR may find an immediate market in libraries, relieving them of some of the problems of storage and retrieval of information. There is also home entertainment.

No doubt the manufacturers look forward to the day when every school and every home has its library of cassettes. They predict a sale of one million cassettes a year by 1971, and since the system is cheap they will probably achieve this. They estimate that the player will cost £100 and each cassette £5, which seems good value, given that the whole *Encyclopaedia Britannica* would only occupy one and a half cassettes.

EVR will bring comfort to the officials of NASA, who have long been predicting the values of spin off from the American space programme. The work of Dr Goldmark and his collaborators at CBS was initiated under a contract from NASA to develop the miniaturization of television for space research.

## Development and Aid

In the annual report of the Overseas Development Institute, the director, Mr William Clark, describes 1967 as a difficult year for those who care about development. The economic difficulties that caused Britain to cut the aid budget also affected the institute's

sponsor companies. The institute was founded in 1960 as a study centre for problems of overseas development, and as an independent advisory body on governmental and other aid. The subsequent establishment of the Ministry of Overseas Development has not, apparently, reduced the need for the institute as a propagandist. Today, more than ever, according to the director, the institute is swimming against the tide of political disenchantment.

The year has seen publications for research works on the French aid programme and on volunteers in development, as well as the first of a series of annual reports on British development policies. The institute seems to pay little attention to the particular problems of scientific aid, despite its all important role in helping developing countries. Its report gives the impression that what makes aid ineffective is inefficient administration in the programmes of donor countries, combined with lack of money. Giving, it would seem, has become a science, and how aid is given seems at least as important as what is given.

## Two Radiotelescopes

THE Dicke panel, set up by the National Science Foundation to decide what new radiotelescopes should be built in the United States, has decided that only two of the six proposals put before it should be accepted, and these two are the simplest and least expensive (see *Nature*, 215, 340; 1967). The panel's decisions, however, seem to be based on sound technical grounds and not because the Johnson administration had put pressure on it to economize in the interests of the war in Vietnam. One of the proposals accepted is for improving, at a cost of about \$3 million, the surface of the hemispherical 300 metre antenna at Arecibo, Puerto Rico, which is administered by Cornell University. This will increase the optimum frequency of the telescope from 68 cm (440 megacycles) to 10 cm (3,000 megacycles).

The other acceptable proposal is for the addition of seven 40 metre dish antennae to the one being built at Owens Valley, California, by California Institute of Technology. The total cost of this is estimated at \$15 million.

For the time being, the panel has suggested that the proposal for a fully steerable parabolic dish 135 metres in diameter put forward by the consortium of twelve universities in the north-east of the United States should be postponed for the time being, chiefly so as to allow an opportunity for experience of radiotelescopes fully enclosed in plastic radomes.

## Much about Meteorites

AN informative and attractive pamphlet *Meteorites—a concise account* by Dr A. A. Moss has just been published by the British Museum (Natural History) at 3s. There are, of course, several authoritative and expensive books on meteorites available to the specialist, but Dr Moss's pamphlet, giving as it does a succinct and very well illustrated account, is designed for the general reader. What is known of the origins, distribution, composition and structure of meteorites is clearly stated and no doubt it will surprise many readers to find that only twenty-one meteorites have fallen on the British Isles. Nothing remains of three of these, which

fell in the seventeenth and eighteenth centuries, but with one exception the British Museum has material from all the others, including a rare iron meteorite which fell in 1876.

## The Sutton Hoo Ship

A photograph of the British Museum archaeologists re-excavating the Sutton Hoo Ship earlier this summer (see *Nature*, 215, 914; 1967).

## Butterflies Fluctuate

THERE has been some alarm about the declining populations of British butterflies such as the meadow brown, which in some places is reduced to one-third of its normal population. All grassland butterflies seem to be rarer this year than previously, but it is not yet certain whether this is more than a temporary decline, for the sizes of populations are often subject to considerable fluctuation from year to year. The adonis blue and common blue butterflies in a particular area may decline to two or three pairs in one season, and numbers may later increase again to two or three thousand. The adonis blue was almost completely removed from some places during the Second World War when tank tracks passed across its breeding ground, but after the tracks were taken away the butterflies recolonized the area and have continued to flourish. Another reason for diminished numbers in a particular area could be that like the silver studded butterfly the species concerned has suddenly moved to another habitat, perhaps between a quarter and half a mile away, after two or three years in one place.

Those species which are now being driven from their habitats when houses are built on breeding grounds may well be able to survive an enforced move to another habitat. This may also apply to butterflies which are being deprived of their food as a result of the use of weedkillers. Most butterflies feed on common weeds, and so they are being driven from areas in which weedkillers are used extensively. Many species are being poisoned by these chemicals, and also by insecticides, which are harmful to a very wide range of insects. The development of more specific insecticides, which kill only particular insect pests, may cut down losses among butterflies. Like all insects, butterflies are able to build up resistance to insecticides, although the speed with which this occurs is dependent on many factors and can vary considerably from insect to insect. The cabbage white butterfly has developed immunity to DDT, and other species may well develop similar properties.

So far, the declining populations of British butterflies are not necessarily more spectacular than would be expected from the normal fluctuations from year to year. Even the decline of two-thirds in the numbers of the meadow brown may not be particularly ominous.

## Put it Down to Sunspots

IN the July issue of the *Canadian Journal of Botany*, Dr Bruce Cumming, of the University of Western Ontario, claims that there is a correlation between periodicities in the germination of seeds and variations in the solar radio flux, which is an indicator of sunspot activity. Seeds of *Chenopodium botrys* were stored in darkness under controlled conditions of heat, humidity and pressure. Each week a certain number were then removed for germination tests, and the percentage germinating was recorded. There was no correlation, apparently, between germination and humidity, pressure, magnetic intensity or the phases of the Moon. There was, however, a close relation between germination frequency and the level of sunspot activity one week before the wetting of the seeds, although linear trends in solar flux and germination were opposite. At the same time, correlation between germination frequency and sunspot activity is expressed in the form of somewhat compressed diagrams—more than a hundred pairs of values have had to be represented on a horizontal scale only 12.5 cm across. Statistical analysis of periodic functions is necessarily complex, and many workers have emphasized the difficulties of comparing periodicities. It is therefore with caution as well as great interest that further details of Dr Cumming's work will be awaited.

## Chinese Fry

THE white amur or grass carp occurs naturally in the rivers of Siberia and China, but it has been introduced into most of Asia where, raised in stews, it is an important commercial fish and source of protein. Unfortunately the fish do not reproduce naturally in southern latitudes. Much of south-east Asia depends for a supply of fry on China, where there is a considerable industry devoted to catching, sorting and exporting the young fish. Naturally enough, countries like Malaya and India would prefer—and may be obliged

to have—a native supply of young fish instead of depending on Chinese sources. Moreover, the Chinese themselves are worried by existing arrangements, if only because they are leading to over-fishing of the rivers, notably the Yangtze Kiang and Si Kiang. Several attempts have been made, both in China and the importing countries, to induce successful spawning of pond reared fish by injecting female carp with fish pituitary gland extract. Apparently it is always the females that are infertile; the males seem to produce normal sperm no matter where they are. In northern latitudes, Japan, Formosa, Manchuria and Northern India, the experiments were successful and in Cuttack in northern India, for example, hundreds of thousands of young grass carp are raised annually.

In more southern countries, however, the outlook is grimmer. Some recent work done in Malacca, at a latitude of 2° 17' N., by Hickling (*Proc. Roy. Soc. Edin., B*, **70**, 62; 1967) shows that it is impossible to induce spawning of fertile eggs. In Malacca, grass carp grow about three times faster than in natural habitats—Hickling's fish gained between 8 and 10 grammes a day, growing from 2 g to between 6 and 7 kg, compared with a gain of 2.8 g a day by river carp in Siberia. This, of course, is what makes the grass carp such a valuable commercial fish. Furthermore, in Malacca the carp mature earlier and at a smaller size and, being so near the Equator in a climate without marked seasonal changes, they do not have a spawning cycle; some fish are ripe at all times of the year. The males shed active sperm, but the females fail to spawn. The ovaries fill with partially developed eggs which eventually atrophy. When Hickling injected female carp with pituitary extract from another cyprinid fish, *Puntius gonionatus*, the ovaries increased in size as the number of eggs increased, but the eggs themselves were still incompletely developed. When shed, none of these defective eggs was successfully fertilized.

Hickling believes that it is the lack of a climatic stimulus—a spring season with rising temperatures and increasing day length—that prevents egg development in Malacca. The synchrony of the breeding season of mammals with periods of increasing or decreasing light intensity is, of course, well documented. It would be interesting to see if, by artificially altering temperature and day length, the carp could be induced to spawn in Malacca. But even if such experiments proved successful the cost would probably prohibit them as a commercial proposition. It seems that the unfortunate Malaysians must remain dependent on an imported supply of carp fry.

## Sedimentology Congress

from a Correspondent

THE seventh International Sedimentological Congress was held in the Universities of Reading and Edinburgh from August 11 to 15 under the general chairmanship of Professor J. H. Taylor, president of the International Association of Sedimentologists; nearly 450 delegates from 41 countries attended. The choice of two conference centres, several hundred miles apart, was justified on the grounds that both Reading and Edinburgh had excellent claims, the former because of its internationally renowned sedimentology laboratory, and the

latter by its illustrious associations and strong traditions in the earth sciences. Both centres were well placed, moreover, for field excursions in the southern and northern parts of Great Britain.

At the congress attention was focused particularly on modern work involving experiments on the hydraulics of sedimentary processes, which should lead eventually to a fuller knowledge of the silting of harbours and estuaries, among other things. The congress was also concerned with the application of sophisticated statistical techniques to the production of simulation models, for example, and to the more accurate prediction of oil, gas and metal-bearing deposits. There was discussion of the geotechnical properties of clays, which have important economic applications in civil engineering. In addition, biological and chemical aspects of sedimentation received full attention, while the more traditional fields of research were not neglected.

There were two major innovations in the organization of the congress which may be of interest to other scientists. First, the proceedings will not be published. Privately, many cynical remarks are expressed about the somewhat gratuitous proliferation of the literature by "symposium volumes", much of which consists of papers summarizing work already published or which is shortly to appear in print in the established scientific journals. Nevertheless, there is widespread resignation at the collusion of publishers and scientists anxious to promote their subject, while the organizers of the Sedimentological Congress have endeavoured to resist. An added advantage is that contributors to public discussions should feel less inhibited if they know that their remarks are not being recorded for posterity. However, to permit as much time as possible for free discussion, contributors had their short papers cyclostyled as preprints for members of the congress, so that their verbal presentation was restricted to a few minutes. These preprints also served the function of "travel vouchers" for those delegates unfortunate enough not to be able to acquire their expenses in other ways.

Secondly, an attempt was made to counteract the frustration that arises at so many conferences when the chairman, operating to a strict time schedule, is obliged to terminate a discussion just when it is becoming lively. Each day of the congress was therefore so organized that, following general lectures by distinguished scientists and formal discussion groups in the various specialized research fields, at which short papers were read and commented on, delegates had the opportunity to convene informal discussion groups at the end of the afternoon session, to pursue further topics that had provoked a widespread interest. There seemed to be general consent that these informal sessions tended to be among the most stimulating of the whole congress.

## New Looks at Disulphide Bonds

from our Correspondent in Molecular Biology

DISULPHIDE bonds are known to play an important part in maintaining the conformation of those proteins—the great majority—in which they occur. When the disulphide bonds of a protein are in the reduced (broken) state, they must be reoxidized before the native

conformation can be regained. It is also generally true that in the native protein they display a considerable, though variable, resistance to cleavage.

Thus in a survey of a large number of proteins, Davidson and Hird (*Biochem. J.*, **104**, 473; 1967) find that the majority cannot be appreciably reduced by glutathione and a few others react to a small extent. When the native structure is weakened or disrupted by heat or limited proteolysis, the disulphide bonds become available for reaction. Now in ribonuclease, which has four disulphide bonds, Davidson and Hird (*ibid.*, 480) find that reduction begins at a temperature of 50° C, but it is observed that the enzyme then becomes a mixture of the fully intact and completely reduced forms. Thus it appears that the reduction of the first disulphide bond is rate-limiting, in that it makes the remainder instantly accessible by (presumably) provoking a conformational collapse. It has not been possible to establish that it is one in particular of the four cystines which acts as a hinge-point for the conformation.

A remarkable case in which differential reactivity of different disulphide bonds is strikingly apparent is reported by Seon (*J. Biochem., Tokyo*, **61**, 606; 1967). This concerns the Japanese enzyme (as one may call it), Taka-amylase A. This molecule has four disulphide bonds and a cysteine residue, which is unavailable to reagents in the native state. When incubated with sodium borohydride as the reducing agent at 80° C, the appearance of titratable sulphhydryl groups with time occurs in a stepwise manner. Although there is some variation between different preparations, the best results show three perfectly developed plateaux. The first corresponds to two titratable groups, deriving from reduction of a single labile disulphide bond; one further group is titrated at the second plateau, and is identified by labelling and peptic digestion experiments as the single hidden cysteine residue of the native protein, which thus becomes available after scission of the first disulphide bond. One implication is that the conformational relaxation is slow compared with the disulphide reduction. The reaction then continues, with at least one further plateau. One of the most curious aspects of this remarkable reaction is the substantial conservation of enzyme activity up to the second plateau. Thus, although a conformational change must occur to liberate the hidden cysteine residue, the enzymatically important parts of the conformation are preserved (or reform in the presence of substrate).

Also in a current article (Pontremoli *et al.*, *Proc. US Nat. Acad. Sci.*, **58**, 286; 1967), a case is described in which the formation of an extraneous disulphide bond by an enzyme may act as a metabolic control mechanism. The enzyme, fructose diphosphatase, is activated by some, though by no means all, disulphide reagents, notably by cystamine which occurs physiologically. The cystamine reacts with the protein via available sulphhydryl groups, and although three cysteamine residues are incorporated, two of these can be removed again, without loss of the newly gained activity. All cysteamine residues are removed, and the enzyme deactivated, by exposure to reduced glutathione, and the authors suggest a coupled feedback scheme, whereby this new method of regulation can function. It is supposed to operate independently of the established process of inhibition by AMP.

# Science, Technology and Society

by

LORD JACKSON OF BURNLEY

Head of Department and  
Professor of Electrical Engineering,  
Imperial College of Science and Technology,  
London

In this extract from his presidential address to the British Association, delivered on August 30, Lord Jackson discusses the impact of the progress of science on society, the kinds of benefit which the public derives from this progress, and the kinds of problem which it creates for the community, for government, and for the scientists themselves.

## The Scope and Problems of Scientific and Technological Policy

THE progress of science and technology is affecting increasingly, if not in large measure determining, the trend of national and international affairs. It is affecting the life and the policies of the highly developed and the developing countries alike and each, in its own context, is seeking urgently to take advantage of the potentialities of this progress. Each is seeking to formulate a scientific and technological policy, by which is meant the systematic consideration up to the highest levels of government of the relationship between scientific research and technological development, and the growth of the economy.

Throughout the post-war period Britain has been in the forefront—indeed it has been second only to the United States—in the proportion of its national wealth which it has devoted to research and development. In 1964–65 the total expenditure was about £750 million, some 2.6 per cent of the Gross National Product. The present figure is approaching £1,000 million per year. As yet no close correlation has emerged between this form of national expenditure and the Gross National Product. Otherwise our national economy would be more buoyant than it is. The fact is, of course, that the effect of research and development on the economy comes from the success with which its results are translated, through design and manufacture, into efficient, reliable and economically competitive new types of industrial products and improved forms of already well established ones. This is not to say that we should spend less on research and development. In fact, the cost of supporting the work of the individual research workers is rising steadily because of the increasing complexity and sophistication of the techniques and equipment nowadays required. But of what we spend, a larger proportion should be spent, in my opinion, within industry. I regard it as of great importance that there should be minimal physical separation between the processes of research and development and those of design and manufacture, although I shall introduce a reservation on this point later. I am therefore pleased that the self-financed expenditure within industry has increased considerably during recent years—from £77 million in 1955–56 to £320 million in 1964–65. To that latter figure was added about £180 million from government sources, mainly in aid of defence programmes, making a total expenditure of £500 million within the overall national figure of £750 million mentioned above.

We cannot reasonably expect, of course, to be in the forefront of all branches of technology. The electrical and chemical industries, for example, have grown considerably during the past few decades; others have remained stationary; and still others have declined in their contributions to industrial output and to the Gross National Product, and in the employment they provide. Industries on which the ascendancy and economic strength of this

country rested some decades ago are now finding it extremely difficult to compete with the corresponding productions of countries which were previously our customers. Clearly, there are many factors outside the scope of this address, including the structure of industry, the quality of its management, the availability of capital, the prevalence of restrictive practices, the increasing industrialization of other countries, which bear on this situation. But it is surely significant that whereas in 1962, the latest date for which I have found comparative figures, the electronics and chemical industries spent close on £200 per annum per employee on research and development, there were other large industries for which the figure was less than £20. I recognize the differences between industries, but if it is necessary in the national interest that our traditional industries should remain vigorously competitive, though perhaps on a reduced and more selective scale, it is surely beyond question that they must draw more fully on the potentialities of scientific knowledge and exploit it technologically with greater effectiveness.

The overall expenditure by government on research and development during 1964–65 was about £430 million of which in addition to the £180 million spent in private industry and public corporations, £250 million was devoted to work in the establishments of the various ministries, and in the universities. This large commitment raises questions for, and decisions by, government as to what the size of the overall budget for the succeeding year should be; the priorities between the different sectors and between competing projects within sectors; the location of work as between industry, government establishments and the universities; the overall co-ordination of the research and development programmes sponsored by different departments of government; the way in which government spending of other kinds should be used to stimulate the concentration of research and development work in industry; and the part which Parliament should play prior to the decisions of individual sponsoring ministries. These are illustrative of the questions which fall within the scope of scientific and technological policy.

I do not think I risk giving offence in saying that no country has yet progressed much beyond the experimental stage in devising means of formulating and implementing its scientific and technological policy. The recent setting up of a Central Advisory Council for Science and Technology, under the chairmanship of Sir Solly Zuckerman, to advise the Cabinet on national strategy for the co-ordination and utilization of the country's scientific and technological resources, is for this country an important further step forward in the process. The subject is not, however, the concern only of scientific and technological experts. It is crucial to the satisfactory progress of the process that Parliament—the representative body of the general public, and the one ultimately responsible to the public for the expenditure of public funds—should understand fully the basis and the criteria on which decisions

on the questions mentioned above have to be taken. It is essential that the members of Parliament should be informed, and become involved, early in the processes of analysis and appraisal leading to the taking of these important decisions. To a rapidly growing extent the background of these decisions is of a highly complex and sophisticated scientific, technical and economic nature. The usual and necessary procedure is for particular questions to be studied, and the case for ministerial and then governmental decision prepared, by the Civil Service staff of the ministry concerned, often with the help of advisory committees composed of experts drawn from outside government service. The danger is that unless Parliament finds a way of getting to grips more effectively with scientific and technological issues, its function will become little more than that of endorsing, on limited information, decisions already taken at ministerial level.

In these circumstances the role of the Parliamentary and Scientific Committee has become increasingly important. Established in 1939, it was until a few years ago a unique body of its kind. Its present membership includes some 130 members of the House of Commons, 60 members of the House of Lords, and nominated representatives of 130 scientific and technological organizations. The new House of Commons Select Committee on Science and Technology, which will be free to call for evidence from any quarter, is likely to exercise a much more direct influence on these matters. I hope that, in supplementation of the work of the Select Committee, the evidence it obtains will be used to stimulate discussion within the professional societies and institutions of scientists and technologists, and indeed within the wider sphere of the general public. A groundswell of informed public discussion in the formative stages would, it seems to me, be an invaluable guide to those responsible for formulating and deciding on major issues of scientific and technological policy.

### Policy for Basic Science

Within the overall national expenditure of £750 million on research and development in 1964-65, there were two components concerned mainly with basic research of long-term significance which call for special comment. One is the expenditure of the Science, Medical, Agricultural and Natural Environment Research Councils, amounting to about £44 million, of which some £28 million was spent in their own establishments, and the remaining £16 million in the universities in the form of research grants, training awards and the support of special units of the councils associated with the universities. The other is the money spent in the universities from their grants from the University Grants Committee, of the order of £40 million, giving a total university expenditure of about £56 million on scientific and technological research. The combined figure of £84 million has grown from about £25 million in 1955-56, at an annual rate substantially in excess of the rate for the overall national expenditure on research and development, and still more so of the rate for Gross National Product.

Inevitably, this has raised the question as to whether the recent rate of increase, around 13 per cent in real terms, can be maintained, and indeed on what criteria any particular rate can be justified. The responsibility for advising government on this aspect of scientific policy—that for science itself—rests with the Council for Scientific Policy, in collaboration with the research councils, and its report of May 1966 discussed the studies it was undertaking in the attempt to establish these criteria. Its task of quantifying and justifying desirable rising expenditure on basic research is indeed a difficult one, and one on which little guidance is available from the attempts of other countries faced with the same problem. Understandably, basic scientists are hesitant about making claims for the benefits resulting from their work, partly because they do not like it to be so assessed, and partly

because the benefits are often fortuitous and long delayed, and invariably depend on other factors falling outside their domain. Nevertheless, some striking examples of benefit to the community can be cited in the fields of all the research councils. I must restrict myself, however, to a brief reference to that of medical science.

Thus the death rate of children in the first year of life has been reduced over the past 50 years from 120 per thousand to 22 for boys, and from 98 to 17 for girls. On the assumption that on average people contribute usefully to the economy over 40 years of their lives, this improvement in infantile mortality now ensures some 3.5 million more years of work than would have been possible by the standards of 1912. Moreover, in 1964 there were alive some 70,000 men and women who would have died from tuberculosis but for the application of effective drugs from 1952. At a conservative estimate, the savings in the cost of hospital care and benefits alone—or their availability for other kinds of patients—are at least £30 million per year.

Many problems of equally great social and economic importance remain to be solved. One out of any five men over 40 years of age will develop coronary thrombosis before reaching the age of 65 years, and one-third of these are unlikely to survive the first attack. The cost to the Exchequer in terms of hospital care, sickness benefits, and widows' pensions was about £45 million in 1964, and the loss to national productivity about £90 million. One out of five women will develop cancer in the course of their lives, and in 1965 105,000 people died from this disease.

To attempt a quantitative justification for basic research in economic or sociological terms in whatever field is, however, precarious. The support for it and its pursuit must, to a large extent, be an act of faith. It may do no more than add to the body of scientific knowledge—to the seedbed from which, in due course, new ideas and new possibilities may hopefully be expected to emerge. There are no guarantees. This is especially the case with much of the research being undertaken within the universities, particularly within such fields as high energy nuclear physics, radio astronomy and microbiology. The leaders of research in these fields are literally probing the unknown, and in seeking support for their ideas and programmes they must rely on the acceptance by government, and by the community, of a number of arguments which may be found intangible. These are that the search for deeper scientific understanding for its own sake is a vital form of intellectual exercise; that the guidance and supervision of young research students are essential parts of the teaching function of the universities, and that, in the absence of research, teaching at the undergraduate level would rapidly be reduced to mere pedagogy; that basic research is a stimulant to, and affords the foundation for, the more objective pursuits of applied science and technology; and that it opens up, from time to time, a quite new field of technological development.

Yet those called on to afford this acceptance are faced with another set of intangibles. What total resources should be allocated to this basic research? How then should this be apportioned between the physical, biological and earth sciences? On what criteria should priorities be determined between the different facets of these main fields? To what extent should the claims of big science be allowed to jeopardize the support of small science? And on what grounds should a national programme be linked with, or subordinated to, participation in an international programme?

The scientific decisions, or recommendations, which lie within this formulation of a policy for science itself can, of course, be made only by scientists, and they are decisions which must now be made in the knowledge that the resources available cannot continue to grow at the rate of recent years, expressed in terms either of finance or, as I shall suggest, of qualified manpower. A continuing increase in expenditure on basic scientific research will be

possible only in so far as the successful exploitation of the results of research already completed makes increasing resources available. Regrettable though this may be to the scientist, the fact is that the strength of our national science has run ahead of the strength of our technology, and that, so long as this situation remains, the continuing strength of our science must be in jeopardy. Unfortunately, this danger is enhanced by the growing evidence that in some fields our technology has run ahead of our industrial and commercial expertise.

The argument has been used that the expanding needs of scientific research would be readily provided for by a tiny reduction in our defence budget, in the egg subsidy, or in our overseas aid. But it may also be argued that the facilities and freedoms which are rightly claimed by the outstanding scientist are regarded nowadays as matters of entitlement by many who are not outstanding and are unlikely to become so, and that we are spreading our available resources too thinly and over a wider range of science than is necessary or sustainable. In basic science, more than in most activities, quality is more important than quantity.

### Manpower Resources for Science and Technology

I believe that the prerequisite for the maintenance of our continued national progress in science and technology is an adequate supply from higher education of well qualified scientists and technologists. In other words, we cannot hope to implement a sound scientific and technological policy without a manpower policy involving the making of assessments, the forming of judgments, and the taking of decisions on the associated requirements for scientists and technologists, and on the means by which these requirements might be met.

Frankly, the present position and the future prospects are not encouraging. In its report of October last, the Committee on Manpower Resources for Science and Technology revealed that over the 1962-65 period the new supply of qualified scientists and technologists, especially of the latter, was inadequate to meet the overall national demand for them, particularly within industry and the schools. Unfortunately, the forecast data for the 1965-68 period afforded no promise of an improvement. Whereas the estimated overall demand of employers by 1968 was given as 24 per cent greater than the 1965 employment figure of about 330,000, it was stated that the new supply from higher education over 1965-68 would not raise this 1965 figure by more than 14.6 per cent. This means that against a requested rise of 7.4 per cent annually there is an assurance of growth from new supply of only 4.6 per cent. Moreover, the recent evidence of entry to the university departments of science and technology, and of the trend away from science in the sixth forms at school, suggests that this 4.6 per cent annual rate of growth is unlikely to be maintained beyond 1968. It is distressing for those who have striven to provide the greatly improved facilities that during the past academic year, according to the Universities Central Council on Admissions, there were 1,600 vacant university places for scientists and technologists. Clearly, employers will have to learn, and quickly, to use more effectively the scientists and technologists they already have.

In circumstances where it is all too easy to blame the schoolmaster, I want to pay tribute to what the quite inadequate number of science teachers have done in their response to the Nuffield Science Project, and in their search for means of teaching science in ways which reveal its technological significance. The development of experimental work aimed at stimulating an interest in technology, as described in the recent report of the Schools Council, *A School Approach to Technology*, is specially commendable.

I would also wish that the teaching of subjects such as history and geography might reflect more deliberately the ways in which scientific discovery and its technological

application have affected the progress of mankind and his use of the natural resources available to him.

The plain facts are that courses in science and technology, or the careers open to graduates in these subjects, are failing to appeal to a majority of the sixth form students who want to attend a university; that among the minority a majority are choosing science rather than technology; and that among the scientists a majority of the best academically are opting for research, preferably within a university. Unfortunately, many of the latter are prepared to emigrate if this wish cannot be met at home to their satisfaction. This is a serious state of affairs, since, uncorrected, it must lead to reduced national prosperity.

The factors affecting the choice of subjects in the schools and the universities are being studied by a committee under the chairmanship of Dr F. S. Dainton, vice-chancellor of the University of Nottingham; and those affecting the choice of first employment by science and technology graduates as between the schools, the universities, government service and industry, by another committee chaired by Dr Michael Swann, principal of the University of Edinburgh. I will content myself here with saying that I would like to see technology presented as a pursuit in which scientific, technical and economic considerations are intimately interwoven with concern for the human problems involved in its impact on the life of the community, both national and international.

There has been much talk in recent years of the two cultures. If these in fact exist, I see technology as a bridge between them, and I would wish it to be taught in a way which reveals and illustrates their interrelationships. I regard technology, so taught, not only as a necessary preparation for a wide range of vocational employments, but as a good preparation for life as it is now evolving. I therefore, as a technologist, welcome such steps as are being taken to reduce the degree of specialization in the final stages of school life and in undergraduate courses in science and technology. This means, of course, that the attainment of a degree in science or technology by no means represents the end of the educational process. I see the attention to changing specializations as a continuing process throughout a career and as involving a much closer partnership between employers and educationalists in the formulation and conduct of advanced courses than has yet been achieved.

And I attach no less importance to the continuation of scientific study at school and at the university by those who have no wish to prepare themselves for careers in science or technology as such. Many such people will inevitably be concerned with, and sometimes be required to take decisions in, situations created by the progress of science and technology, whether or not this country remains in the forefront of initiative in them. I appreciate the difficulties since, while the scientist and technologist can readily be helped to draw on the vast accumulation of literature in sociology and the arts, there is as yet little literature in science and technology which is well suited to the alternate purpose. Here is a field of research which should be tackled as a matter of urgency.

### Science, Technology and the General Public

Whatever may be done within the sixth forms of the schools, and in the undergraduate courses of the universities, cannot, however, increase the output of qualified scientists and technologists in the near future. It is essential, therefore, to focus attention on the effectiveness with which we are utilizing the ones we already possess. This involves consideration of whether these are distributed to the best national advantage between the schools, universities, government service and industry; whether there is adequate collaboration and mobility between the qualified manpower in these sectors; whether they are being given sufficient encouragement in status and salary and sufficiently attractive career prospects; whether

they are being assisted adequately by well educated and trained technicians and other supporting staff, etc. These are not, of course, new questions, and they are certainly not being neglected by those on whom the responsibility for decision and action rests. It may be doubted, however, whether we are moving rapidly enough towards their resolution.

And yet a basic trouble may be that notwithstanding our shortage of qualified scientists and technologists, the situation being created by those we already have is moving faster than lies within the competence of the community at large to comprehend and to adapt itself to. The community is expecting, if not demanding, a continuously rising standard of living without, apparently, understanding sufficiently the essential origins and the requirements of this improvement, and the consequences which are associated with it. The essence of the matter is that our expectations are rising faster than our effort and our co-operativeness.

Two of the post-war developments within my own subject which are changing the conditions of employment, and the kinds of skill relevant to it, for many people are those of automation and the electronic digital computer. Basically, there is nothing new in this situation; it has characterized the progress of technology, and the process of mechanization, throughout history. What is new is the rapidity with which the change is occurring, and the scale and urgency of the problems it is posing for attention. Popular opinion has it that the automatic control of industrial processes merely reduces the number of people employed, and therefore is a cause of unemployment. Indeed, as the Duke of Edinburgh said in a recent speech, "In this country the labour employed for the same output has been reduced to between one-tenth and one-fifteenth since the turn of the century". But he then said: "The point, of course, is in the words 'for the same output'. Without technological advance and automatic control we would need a labour force of hundreds of millions to produce the volume of consumer goods which we now take for granted." And I might myself add that many, or most, of them would not be available at all.

The Industrial Training Boards set up for different industries to implement the Industrial Training Act are as yet preoccupied with the formulation of schemes and the provision of facilities for the satisfactory initial training and associated further education of new recruits to industry at the craft, technician and professional levels. A primary aim of these schemes must be to ensure ready adaptability to changing situations and an appreciation of the likelihood that re-preparation for different work will arise periodically in later life. I understand that in Sweden 1 per cent of the working population are regularly in process of re-training. We are a long way from this, and we shall be wise to prepare to deal with a still larger proportion of our own. It is important that the provision should not be wholly vocational since a further consequence of technological progress is increasing leisure—and not least for many who have not yet learned to use to good communal advantage the leisure time they already possess.

### Conclusion

I have been able here to touch on only a few of the problems which the progress of science and technology creates for society. This progress impinges on, and raises issues of, moral as well as material concern over the whole range of human interest and activities. The destructive potentialities of nuclear power, the availability of harmful drugs, the increasing sophistication of crime, and the fantastically expensive aero-space race of the United States and Russia, while vast problems of human welfare are in urgent need of resolution even in their own countries, are a few examples.

A likely reason why science and technology are proving

less attractive to young people than I have been arguing is essential for this country on economic grounds may well be that they, reflecting a widespread feeling within the community, sense a lack of concern by scientists and technologists for these wider issues. In my experience this is by no means the case. Nevertheless, it must often appear, and indeed it is not infrequently a fact, that the anticipation of and the preparation for the consequences of technological change lag considerably on the urge to achieve it. The Select Committee of the House of Commons on Science and Technology, to which I referred earlier, carries a heavy responsibility in respect of Government sponsored projects in this regard. But in my belief the technologists themselves have an important part to play, by focusing early attention on the likely sociological effects of what they are seeking to achieve, and by ensuring that the knowledge and experience of sociologists and others are brought to bear in joint consideration of the problems involved. We must aim for a much closer identification of the social scientists with emergent technological possibilities, so that there may grow alongside innovation and change the ability to anticipate and to plan ahead the resolution of the human problems associated with it.

I wish I were competent to portray the kind of community we should be seeking to create with the aid of the immense potentialities of science and technology. I am sure that the strengthening of our technology is only one of the means of its attainment. But I am convinced that it is an indispensable means, and that only through the material resources that will flow from successful technology shall we be able to afford to do the things that most need doing. What I feel the public lacks is a clear enough conception of the things that most need doing and an understanding of the part which technology would play in the doing of them.

To make my final point, prominent among these I would place the need to continue to help the emergence of the developing countries, and to exercise the influence in international affairs for which I believe we have a special responsibility and talent. Our scientists and technologists have become not only the guardians and guarantors of our national economy, but also the agents of a new diplomacy in which much more than an expanding export trade is at stake. They will have an increasing part to play as advisers and teachers in the progress of the developing countries, and must not only carry conviction as experts in their respective scientific and technological specialities, but must also gain respect as ambassadors of broad and sympathetic vision, sound judgment and unassailable integrity. This country has a great international job still to do—unfortunately, it is at present uncertain whether we shall be able to find enough scientists, and more particularly technologists, to help ensure that we remain in a position to do it.

For over a century the British Association for the Advancement of Science has attempted to inform the general public of new developments in science and technology, and to stage discussions on the impact this is having, or is likely to have, on the life of the community. Its work in these respects is now being greatly supplemented by the increasing attention being paid to science and technology by the sound broadcasting and television services and by the daily Press. In close collaboration with these agencies the Association still has an extremely important part to play, and the six symposia, on matters of great public moment, which have been included in the programme of this Leeds meeting, and other developments being planned for next year in Dundee, are evidence of its continuing vitality. My concluding sentence must be to express my sense of the honour which attaches to the Presidency of this historic and distinguished Association; to thank those who were responsible for inviting me to occupy this office; and to wish the Association a long and successful future.

# Effects of the Numbers and Sizes of Platelet Aggregates on the Optical Density of Plasma

by

G. V. R. BORN  
M. HUME

MRC Thrombosis Research Group,  
Department of Pharmacology,  
Royal College of Surgeons,  
Lincoln's Inn Fields, London

The formation of platelet aggregates in plasma affects its optical density. The relationship between the optical density and the numbers and sizes of aggregates has been explored.

In 1962 a photometric method was introduced for the quantitative investigation of the aggregation of blood platelets<sup>1,2</sup>. A beam of light is directed through a suspension of platelets in plasma or in an artificial medium, the optical density of which is continuously recorded by measuring the transmitted light. The suspension is stirred at a rate rapid enough to make the collision rate of the platelets non-limiting but not enough to damage them. When the platelets aggregate the amount of transmitted light increases and when the aggregates disperse the amount decreases. With this method and its modifications (for example refs. 3-5) much new knowledge has been obtained about the mechanism and significance of platelet aggregation. The method itself, however, remained entirely empirical in so far as nothing was known about the way in which changes in light transmittance depended on the concentration and magnitude of the platelet aggregates formed. The experiments described here were carried out to provide information about this.

Blood was collected by puncture of the antecubital vein and mixed with one-tenth the volume of 3.8 per cent trisodium citrate (0.129 molar). The blood was centrifuged at room temperature for 10 min at 226*g*. The supernatant of platelet-rich plasma was transferred with a Pasteur pipette to siliconed glass bottles. The plasma was kept at room temperature until used. Platelet aggregation was measured in a modified EEL long-cell absorptiometer differing from the apparatus used by Haslam<sup>5</sup> in that it had in the sample tube a magnetic stirrer covered with polyethylene which was driven from below by a magnet rotating at about 1,000 r.p.m. A simple attenuator and back-off circuit was employed to connect the output from the photocell to a pen recorder of either 10 mV or 1 mV full-scale sensitivity. Samples of 1 ml. of platelet-rich plasma were pipetted into glass tubes treated with silicone, 10 × 50 mm, which were then warmed at 37° C for 5 min and inserted into the water-jacketed compartment, also at 37° C, of the absorptiometer. The recorder chart was calibrated between 10 and 70 per cent transmission with platelet-free plasma from the same blood sample set at 100 per cent.

Reagents were added to the plasma samples in the absorptiometer in volumes of 50  $\mu$ l. or less with microsyringes. Adenosine diphosphate (ADP) sodium salt was stored in the deep freeze as a 50 mmolar solution neutralized to pH 7.0 with sodium hydroxide. Dilutions of 1 mmolar were made in *tris*-saline (139 mmolar sodium chloride, 15.4 mmolar *tris*-(hydroxymethyl)aminomethane hydrochloride, pH 7.4) and stored in the deep freeze for up to 1 month. Further dilutions were made in *tris*-saline on the day of use. Desmethylinipramine (Pertofran, Geigy) was dissolved in *tris*-saline; stock solutions of 10 mmolar were stored in the deep freeze.

Before and at different times after adding ADP, aggregation was arrested by adding one-tenth of the

volume of 10 per cent formaldehyde in saline. At the moment of addition, the pen-recorder tracing showed an injection-dilution artefact; all change in light transmittance ceased within 2 sec, indicating that mixing was then complete. The formalinized samples were diluted with 1 per cent formaldehyde in saline up to five-fold, depending on the light transmittance at the time the reaction was stopped. This was done to facilitate counting and to aid in deciding whether adjacent platelets were actually adhering to each other in aggregates or were merely lying close together.

Platelets and aggregates were counted in the improved Neubauer phase contrast haemocytometer. The haemocytometer was cleaned successively with soap and water, methanol and acetone, and wiped dry with an electrostatic cloth. The cover slip and the chamber were examined with a hand magnifying glass to ensure that particulate matter was not present. To determine the initial platelet count, a sample of platelet-rich plasma was diluted 100-fold with 1 per cent ammonium oxalate. Fifty small boxes of squares were counted (both sides of the chamber), usually about 850 platelets in all.

The diluted formalinized plasma samples were thoroughly mixed and transferred to the exact centre of the haemocytometer. Using small forceps, the coverslip was carefully placed on the chamber so as to avoid trapping air bubbles or asymmetrically displacing the sample. The chamber was then examined under the phase contrast microscope to make sure that the distribution of aggregates in the central area was representative of the entire sample and that no bubbles or particles of lint were in this area. Two hours were permitted to elapse for the complete settling of platelets and aggregates. If by this time all single platelets did not lie within the same plane of focus, further time was allowed for settling. The entire central ruled area, that is twenty-five small boxes of squares, was photographed together with a microscopic calibration scale. In samples showing maximum second-phase aggregation the photographed area was doubled. Prints were made of the whole area at a final magnification of  $\times 250$  and joined in a montage. Parallax was minimal and did not affect the number of cells counted. Individual platelets together with those in small aggregates containing between two and eight platelets each were referred to as "countable platelets". These were counted in one section of each of the photographs of all samples, and the results were recorded before counting the next adjacent section of all samples in turn. This counting procedure was used to minimize bias, and the results of the counts were added at the end.

Aggregates in which individual platelets could not be counted reliably had to be measured differently. The photographic negatives were projected at the same magnification ( $\times 250$ ) onto sectional graph paper. The

periphery of each aggregate was traced and the enclosed area was measured in  $\mu^2$  by reference to the calibration scale. All measurements were then corrected for dilution.

The dense aggregates were irregular in shape. By dividing the total area of mapped aggregates by their number, an area in  $\mu^2$  was calculated for a hypothetical "mean circular aggregate". From the radius of the "mean circular aggregate" the volume in  $\mu^3$  was derived of a hypothetical "mean spherical aggregate". The number of platelets in all the dense aggregates was estimated by subtracting the number of countable platelets from the platelet count of the original suspension. This estimate was divided by the number of aggregates, and the resulting number was divided by the volume of the "mean spherical aggregate" to obtain an estimate of its density, expressed in platelets/ $\mu^3$ .

An important discovery made recently by means of the photometric method was the demonstration that the specific aggregation by ADP of human platelets at 37° C occurs in two phases<sup>8</sup>. The first phase is reversible and competitively inhibited by certain substances closely related to ADP<sup>2,7,8</sup>. The second phase is caused by the release of ADP from the platelets (unpublished work of Mills and Roberts) in a chain reaction<sup>9</sup>; it is irreversible but can be prevented by chlorpromazine, imipramine, and some related drugs<sup>10</sup>. It was clearly necessary to establish the relation between aggregates and light transmission in both phases separately; this was done as follows.

The concentrations of ADP added to different plasmas were chosen to permit the taking of samples at different points during the changes in light transmission which indicate the first and second phases of aggregation. In the first experiment (Fig. 1a), ADP was added at a concentration of 1  $\mu$ molar which, in this plasma, brought about a slow increase in light transmission amounting to only 7 per cent after 75 sec. By this time, 87 per cent of countable platelets had disappeared and many larger aggregates had formed. The density of these aggregates showed no significant change.

In the second experiment (Fig. 1b), desmethylinipramine was added to the plasma at a concentration of 50  $\mu$ molar to inhibit the second phase of aggregation. When ADP was then added at a concentration of 2  $\mu$ molar, light transmis-

Fig. 1. Light transmittance, countable platelets and aggregate density related to time after adding ADP (see text).  $\Delta\%$  = change expressed as per cent of original value.

Fig. 2. Platelets countable as singles, doubles ( $\times 2$ ), triples ( $\times 3$ ), and so on related to change in light transmittance and time after adding ADP (see text).

sion increased by 15 per cent in 40 sec after which it decreased again indicating reversal of aggregation. During the increase in light transmission the number of countable platelets decreased by 90 per cent; during the reversal it increased by 15 per cent. This time the increase in light transmission was accompanied by a marked increase in the density of the aggregates which also reversed subsequently. During the reversal there was an increase in the number of aggregates, which indicated that they were fragmenting and releasing countable platelets.

Another sample of the same platelet-rich plasma was used to find out what occurred during the second phase induced by the addition of ADP in a concentration of 1  $\mu$ molar without the previous addition of desmethylinipramine (Fig. 1c). The optical record was similar to that shown in Fig. 1b for the first 45 sec; thereafter the light transmittance, instead of decreasing, continued to increase. During the first phase the number of countable platelets diminished, as before, by about 90 per cent. During the second phase, a further small diminution in the number of countable platelets was accompanied by a striking increase in the density of the larger aggregates.

The effect of ADP on the distribution of countable platelets is shown in Fig. 2. Immediately after the addition of ADP, the number of single platelets diminished sharply. At the same time, there was a transitory increase in the number of aggregates containing from two to six platelets. This was seen at a time when the light transmittance had hardly begun to increase (Fig. 2b). By the time the transmission increased by more than about 2 per cent, the number of these small aggregates was already diminishing (Fig. 2a and b). As light transmission increased further the number of single platelets as well as the number of small aggregates continued to decrease.

The experiments were done in an attempt to interpret the changes in light transmittance which form the basis of the photometric method for measuring platelet aggregation in terms of the numbers and sizes of the aggregates formed. It was possible to count platelets in small aggregates containing no more than six to eight platelets but not in larger aggregates which had therefore to be measured in a different way. On the assumption that the average diameter

of the large aggregates was the same in all dimensions, the total area of these aggregates was measured to provide a basis for calculating their total volume. From this it was possible to calculate the density with which the platelets were packed in the aggregates. We therefore counted the platelets in the small aggregates and measured the total area of the larger aggregates. Both measurements could be used throughout the period of aggregation; however, there was no simple way of combining and relating them together to the light transmittance at any given moment.

The results showed that the increase in light transmittance was associated with two effects, namely, the formation of aggregates and their increasing density. Formation of platelet aggregates began before there was any change in light transmittance. During this time the concentration of single platelets decreased steeply as they associated to form small aggregates. The number of these aggregates passed through a maximum about the time when the light transmittance began to increase. The subsequent increase in transmittance was associated with a progressive diminution in the numbers of both single platelets and small aggregates and the formation of fewer, larger aggregates in which the platelets were no longer countable. During early aggregation the density of the aggregates was low, indicating that the platelets were packed loosely with considerable space between individual platelets. This agrees with measurements of the plasma space in early aggregates which is 0.3–0.4  $\mu\text{l.}/10^8$  platelets or 30–40 per cent by volume (unpublished work of Born).

So long as light transmittance increased only slightly, the diminution in countable platelets was not accompanied by a change in the total area of the large aggregates. By contrast, when the light transmission increased rapidly, the total area of the large aggregates diminished markedly, indicating that the density of the aggregates was increasing. These observations establish that the initial velocity of increase in light transmittance is a measure not of the

rate of formation of small aggregates from single platelets but of large aggregates from small aggregates. Furthermore, a high initial velocity is caused much more by aggregate contraction than by aggregate formation.

The observed increase in aggregate density has two possible explanations. Either the volume of the individual platelets decreased, for which the experiments provide no evidence; or the distance between the platelets in the aggregates became smaller. The latter hypothesis is supported by the following consideration. Normal human platelets have a mean volume of  $5.8 \mu^3$ ; in the presence of ADP (0.5–2  $\mu\text{molar}$ ) the volume increases to 7.2 (ref. 11). From this it is possible to calculate the density of aggregates in which the platelets are so tightly packed that no space remains between them. The reciprocal of 7.2 is 0.139 which is the number of platelets/ $\mu^3$  under the influence of ADP, that is, when aggregated. In the experiment shown in Fig. 1c, the corresponding calculation at maximum second phase aggregation gave a value of 0.125 platelets/ $\mu^3$ ; this approaches the theoretical value for a tightly packed aggregate. Whether or not this explanation accounts for the contraction of the large aggregates, its cause remains to be established.

Our findings suggest that any mathematical expression for the relation between the light transmission and the aggregation process is bound to be complex.

## Surface Topography of Ice Sheets

by

G. de Q. ROBIN

Scott Polar Research Institute,  
Cambridge

The idea of predicting the thickness of an ice sheet directly from surface slope can be misleading. The slope of the surface now appears to be related not only to the thickness of the ice but also to changes of longitudinal stress resulting from movement of ice over varying bottom slopes.

THE hypothesis<sup>1,2</sup> that, provided conditions are uniform around the point of observation, the thickness of an ice sheet or glacier is inversely proportional to the surface slope has proved a useful approximation in many areas. Over certain regions of polar ice sheets, however, the hypothesis does not fit the observations<sup>3,4</sup>. The use of methods of continuous radio echo sounding<sup>5</sup> has now provided information which makes a more detailed study of this problem practicable along a line of ice flow to the south of Camp Century (77° 11' N., 61° 08' W.) in North Greenland. We have found that surface slopes can vary rapidly in response to changing longitudinal stresses caused by ice moving over undulations of the sub-glacial floor. A relationship between surface slopes and variations of stress along the line of flow is derived from elementary considerations. This relationship provides a satisfactory numerical explanation of observations when stress changes are averaged over a distance of the same order as the depth of ice. This article describes the basic concept which is used and shows how it works in practice. I. F. Collins (personal communication) has used a rigorous mathematical approach to the same problem and showed the approximations involved in using the simple concept.

It has been generally accepted, following papers by Nye<sup>1,2,6</sup>, that the shear stress  $\tau$  on the bed of a glacier is given by the relationship

$$\tau = \rho g h \alpha \quad (1)$$

where  $\alpha$  is the surface slope,  $\rho$  the density of ice,  $g$  the value of gravity and  $h$  the thickness of ice. The reason why the surface slope rather than the bottom slope controls the shear at the bed is because ice moves as an incompressible fluid. One readily appreciates that a surface slope is necessary to cause water to flow, whatever the slopes of a lake or river bed may be.

When considering glacier flow, however, we are dealing with a non-Newtonian viscous material which can support stress gradients along the line of flow. A recent theory of glacier flow<sup>6</sup> takes account of stresses associated with longitudinal strain rates throughout a glacier. In Nye's model, these strain rates do not vary with depth or along the line of flow and thus longitudinal stress gradients are not considered. The theory provides an explanation of the deformation of a borehole which is more consistent with laboratory studies of the deformation of ice<sup>7</sup>, however, than the first attempts to

Fig. 1. Forces and stress components involved in the flow of an ice sheet over bedrock of varying slope.

explain borehole results on the basis of simple pseudo-hydrostatic theory<sup>8</sup>. Even with the inclusion of a constant longitudinal strain rate, equation (1) still holds, but as in earlier papers the stipulation for this to apply is that the physical conditions (for example, surface slope and ice depth) must not vary much in a distance of order  $h$  around the point of observation. In practice there are many places on glaciers and ice sheets where conditions do vary considerably over distances of this order. In order to tackle the problem we must take account of the variation of longitudinal strain rates and stresses along the line of flow of a glacier.

Longitudinal strain rates in a glacier (Fig. 1) are produced by the differences of stress in the  $x$  and  $y$  directions ( $\sigma_x - \sigma_y$ ). The basic assumption which is needed to justify the approach and procedure of this paper is that the stress difference ( $\sigma_x - \sigma_y$ ) is large compared with the shear stress  $\tau_{xy}$  throughout the ice, or in terms of mean values that  $\sigma_x - \sigma_y \gg \frac{1}{2} \tau$ . Our numerical analysis indicates that  $\sigma_x - \sigma_y$  lies between 1.8 and 3.0 bars for 93 per cent of our calculated values while  $\frac{1}{2} \tau$  varies from 0.3 to 0.4 bars; thus the basic assumption is reasonable. Collins shows that in this case we can consider the vertical stress as equal to the weight of overlying ice at all points, provided that bedrock slopes are not too great (say,  $< 10^\circ$ ). Consequently, the most important variations of ( $\sigma_x - \sigma_y$ ) along the line of flow are caused by changes of  $\sigma_x$ , and to emphasize this we will write  $(\sigma_x - \sigma_y) = \sigma_x^\circ$  where  $\sigma_x^\circ$  thus represents the departure of the longitudinal stress ( $\sigma_x$ ) from the weight of overlying ice at any point. Because longitudinal strain rates vary as ice moves over the varying slopes of bedrock (Fig. 1), so must our value of  $\sigma_x^\circ$ .

To relate  $\sigma_x^\circ$  to the surface slope, consider the forces on a slab of unit width along the line of ice flow extending from  $x_1$  to  $x_2$  (Fig. 1). We can consider the forces on either end as resulting from a hydrostatic term plus a longitudinal component force  $F_L$  due to the stresses defined by  $F_L = h \bar{\sigma}_x^\circ$  where the bar denotes the mean value throughout the ice thickness. If we add these forces to equation (1), which already incorporates the effect of hydrostatic pressure, we obtain

$$\alpha g h \alpha = \tau - \frac{dF_L}{dx} \quad (2)$$

We can then write

$$\frac{dF_L}{dx} = \frac{d(h \bar{\sigma}_x^\circ)}{dx} = \bar{\sigma}_x^\circ \frac{dh}{dx} + h \frac{d\bar{\sigma}_x^\circ}{dx}$$

It is clear from an evaluation of our results from Greenland that variations of longitudinal stress along the line of flow are the dominant cause of variations of our component longitudinal force  $F_L$ , that is  $\bar{\sigma}_x^\circ \frac{dh}{dx} \ll h \frac{d\bar{\sigma}_x^\circ}{dx}$ , so to a first approximation we can write equation (2) as

$$\alpha = \frac{\tau}{\rho g h} - \frac{1}{\rho g} \frac{d\bar{\sigma}_x^\circ}{dx} \quad (3)$$

The approximations involved in use of this equation will be set out in detail by I. F. Collins (in a future paper). Equation (3) has, in effect, been used by Lliboutry<sup>9</sup> as a more precise means of determining  $\tau$  than is given by equation (1). He did not, however, discuss the approximations involved or check his conclusions by direct measurement of  $\tau$ . The attraction of expressing equation (3) in terms of surface slope is that this can be measured and used to check the equation. The last term of equation (3) which we write as

$$\alpha_F = - \frac{1}{\rho g} \frac{d\bar{\sigma}_x^\circ}{dx} \quad (4)$$

shows the effect of longitudinal stresses on surface slopes. If the longitudinal stresses are of constant value along a flow line,  $d\bar{\sigma}_x^\circ/dx = 0$  and equation (1) applies as already mentioned.

Our derived values of  $\alpha_F$  will depend on the type of flow law used to relate  $\bar{\sigma}_x^\circ$  to the strain rate, in order to evaluate the term  $d\bar{\sigma}_x^\circ/dx$ . For example, with a Newtonian flow law,  $\bar{\sigma}_x^\circ$  would vary linearly with strain rate, and variations of surface slope would be directly proportional to variations of bottom slope, even in regions when the strain rate changed sign. Alternatively, if ice is treated as a simple plastic solid with a yield stress in shear of 1 bar, the only permitted values of  $\bar{\sigma}_x^\circ$  on our simplified model would be  $\pm 2$  bars. The term  $d\bar{\sigma}_x^\circ/dx$  would then only affect surface slopes when longitudinal stresses changed sign, the total stress change being  $\pm 4$  bars so that the effect on  $\alpha_F$  would be large. Use of a more realistic flow law, which involves a strain rate dependent on the fourth power of stress, will produce an effect intermediate between the plastic and Newtonian cases. Slope variations ( $\alpha_F$ ) of limited magnitude will be present in regions where the strain rate does not change sign, while large changes of slope are to be expected when strain rates change sign. This fits the character of our observations in Greenland.

The chief difficulty to be faced with our data is that of producing realistic values of longitudinal strain rates ( $\dot{\epsilon}_x$ ) as no direct measurements are available along our profile. We can, however, produce estimates if we make the steady state assumption that the thickness of ice does not change with time, so that the known rate of accumulation ( $\dot{a}$ ) over this part of the ice sheet<sup>10</sup> is compensated at all points by the outward velocity ( $v$ ) of ice movement. Keeping to a two dimensional approach, we have

$$v = \frac{1}{h} \int_0^x \dot{a} dx \quad (5)$$

where  $x$  is the distance from the start of ice movement—which is considered to begin at the crest of the ridge close to Camp Century, as shown on contour maps<sup>10</sup>. Because we know both the thickness of ice  $h$  and the rate of change of ice thickness,  $dh/dx$ , we can also use the steady state assumption to estimate the strain rate  $\dot{\epsilon}_x$ , assumed constant at all depths, from

$$\dot{\epsilon}_x = \frac{1}{h} \left( \dot{a} - v \frac{dh}{dx} \right) \quad (6)$$

To convert  $\dot{\epsilon}_x$  to a stress we use Glen's experimental data<sup>7</sup> relating strain rates to a uniaxial stress. We express this in the form

$$\bar{\sigma}_x^\circ = (\sigma_x - \sigma_y) = b(\dot{\epsilon}_x)^{\frac{1}{4}} \quad (7)$$

where  $b$  is treated as a constant, obtained by extrapolation of Glen's data to appropriate strain rates and ice temperatures. A correction of +20 per cent has to be added to the uniaxial stresses of Glen's data because in an ice sheet we assume the strain rate in the third dimension to be zero.

This procedure neglects the effects of shear stresses  $\tau_{xy}$  in deriving values of  $\bar{\sigma}_x^\circ$ . In principle, the method of success-

ive approximations described by Nye<sup>11</sup> could be used to take into account the effect of shear stresses but this was not practicable. Neglect of this factor could cause errors of up to +20 per cent in our estimates of  $\bar{\sigma}_x$ .

Although strain rates are assumed constant at all depths, the calculations of stress take account of variations in temperature with depth as estimated from the analysis of steady state temperature profiles given by Robin<sup>12</sup>, using data for Camp Century. Recent direct measurements of temperatures down to bedrock (Hansen, private communication) show that observed temperatures are similar to estimated, the maximum difference being 4° C at bedrock. These differences will not significantly affect the value of "b" derived for Camp Century which is 14.8 bar yr<sup>-1</sup>. This is very close to the value of 14.6 bar yr<sup>-1</sup> obtained from Nye's more rigorous calculations of  $(\sigma_x - \sigma_y)$  mentioned here, which were made for thicker ice but a similar temperature profile. Although temperatures deep in the ice must vary somewhat along the line of our profile (Fig. 2) the temperatures at 10 m depth only change from -24.5° C at 0 km to -20.1° C at 48 km; thus we have treated "b" as constant throughout these

calculations. Having obtained a series of values of  $\bar{\sigma}_x$  from (7) we then calculate slope variations from (4).

Our calculations showed that velocities of movement given by the steady state assumption of equation (5) vary from 1 m/yr at 0 km on the profile in Fig. 2 to 10 m/yr at 25 km and 24 m/yr at 46 km. Smoothed values of accumulation were used and ice thicknesses were read off the continuous film record every 220 m of traverse. The mean value of ice thickness from the outward and return journeys was used to determine values of  $\delta h/\delta x$  over distances  $\delta x = 880$  m, which are of similar magnitude to the ice thickness. Overlapping intervals were used to obtain a value of  $\delta h/\delta x$  every 220 m.

In calculating  $\alpha_F$  from (4) we again use overlapping intervals of  $\delta x = 880$  m and calculate  $\alpha_F$  every 220 m. Because small errors or irregularities in the bed produce considerable fluctuations in  $\alpha_F$ , we introduce further smoothing by taking a running mean of  $\alpha_F$  over five adjacent points, as shown in Fig. 2C.

Over the section of the profile from 27 to 44 km the calculated values of  $\alpha_F$  shown in Fig. 2C were found to vary much more than the observed surface slopes; therefore a

Fig. 2. A, Profile of the Greenland ice sheet along the estimated line of ice flow for a distance of 46 km south of Camp Century (77° 11' N., 61° 08' W.). B, Estimated strain rates ( $\dot{\epsilon}_x$ ) along the profile of A above. The full line shows strain rates calculated from equations (5) and (6) on the steady state assumption. The dashed line shows strain rates calculated on the assumption that velocities of ice movement are one half of those given by the steady state assumption. C, Comparison of observed surface slopes (heavy line) with the slope variations  $\alpha_F$  (thin line and points) calculated on the assumption of a steady state model. Calculated slope variations ( $\alpha_F$ ) derived from equation (4) are indicated by the points. They are based on the change of ice thickness between soundings 880 m apart. The continuous thin line shows smoothed values of  $\alpha_F$  obtained from a running mean of five adjacent points. D, Comparison of the same observed surface slopes (heavy line) with calculated slope variations (thin line) of 27-45 km using half the velocities of ice movement given by the steady state assumption (see dashed line in B).

second set of calculations was made for this section using the same accumulation rate but half the velocities of ice movement given by the steady state assumption. The calculated slope variations caused by these slower ice velocities are shown in Fig. 2D.

A profile of the top surface was obtained by using two Wallace and Tiernan altimeters, read by separate observers at intervals of 220 m along the route. Slopes have been calculated from the changes of altimeter readings over 440 m intervals centred on each 220 m. The difference between slopes measured on the outward and return journey over the section from 0 to 27 km averaged  $2 \times 10^{-3}$ . Figs. 2C and 2D show the mean of the slopes measured in the two directions. Isolated changes of slope  $2 \times 10^{-3}$  may result from random errors, but the errors of mean slope over 1 km should not exceed  $10^{-3}$ .

Fig. 2A shows the ice sheet profile along the estimated line of ice flow south of Camp Century and Fig. 2B the estimated strain rates, while Figs. 2C and 2D compare the observed surface slopes with calculated values of  $\alpha_F$ . The vertical displacement between the curves in both (C) and (D) is due to the term  $\tau/\rho gh$  in equation (3) which is the term usually considered to control surface slopes.

From 0 to 25 km along the profile the strain rates are positive at all points, and no major changes of surface slope are present. There is rough agreement between observed and calculated slope variations, possibly as much as can be expected from a two dimensional study of a problem which should really be studied in three dimensions.

The large changes of surface slope of 26–46 km are primarily associated with changes of sign of the estimated strain rates. A large rise in the positive strain rate between 26.0 and 26.8 km only decreases the smoothed value of  $\alpha_F$  by  $7 \times 10^{-3}$  whereas  $\alpha_F$  rises to  $27 \times 10^{-3}$  at 27.7 km due to the strain rate becoming negative at 28.0 km (Fig. 2C).

The lower velocities used for calculating  $\alpha_F$  in Fig. 2D result in fewer changes of sign in the calculated strain rates (dashed line, Fig. 2B). This produces a significantly better fit from 29 to 46 km. This does not apply between 26 and 29 km where a better fit is given in Fig. 2C. We therefore suggest that the ice movement ranges from around 8 m/yr at 26 km to 12 m/yr at 46 km. These velocities are lower than those given by the steady state assumption, possibly because of channelling of ice flow away from our profile towards outlet glaciers, or because outflow of ice is less than the surface accumulation over the region.

Although the process of picking a suitable velocity of ice movement to produce values of  $\alpha_F$  which fit the observed slopes may seem an arbitrary way of producing the right answer, the velocities suggested appear to be of the correct order. An existing theory<sup>13</sup> based on equation (1), when dealing with ice flowing over a ridge of a height of one-tenth of the ice thickness, predicts a change of slope of only 14 per cent compared with an observed change of slope by a factor of six for such a ridge at 27 km on our profile. The factor of six is explained adequately by taking longitudinal stress variations into account.

A second type of theory which involves plastic bending of a glacier<sup>14</sup> also fails to predict the very large changes of surface slope which are involved when the longitudinal strain rates change sign. It is this crucial point which gives confidence in the explanation outlined here. Further testing of our deductions will be provided when measurements of surface velocities and strain rates along the profile in Fig. 2A are completed this year by Mock<sup>15</sup>.

In general terms, equation (3) appears to provide a satisfactory explanation of both local and regional slopes of polar glaciers. The term  $\alpha_F$  can govern slopes over short distances, but because  $\sigma_x$  is unlikely to exceed  $\pm 3$  bar average stress changes over long distances must be

small, as must average values of  $\alpha_F$ . Thus over distances of 100 km average slopes will depend primarily on the term  $\tau/\rho gh$ . The effect of velocity on strain rates, shown in equation (6), also implies that bottom irregularities will have less effect on surface slopes near the centre of ice sheets where movement is slow than towards the edge of ice sheets where movement will be greater. This fits the general character of the levelling profile across central Greenland carried out by the Expedition Glaciologique Internationale au Groenland in 1959 (ref. 16).

Another point which appears justified by our results is the use of Glen's flow law<sup>7</sup> at strain rates around  $10^{-4}$  yr<sup>-1</sup> in cold ice, even though this involves extrapolation to one-thousandth of the lowest strain rates in laboratory experiments.

It must also be pointed out that more severe restrictions should be placed on use of equation (1) than have been applied in practice during recent years. Clearly if the upper or lower surfaces of the ice show appreciable curvature, the term  $d\sigma_x/dx$  becomes significant and equation (1) is inapplicable. A better stipulation would be that  $dh/dx$  and  $\alpha$  should not change in a distance of order  $h$  around the point of observation, or more simply that curvature of the surface should be negligible over any area to which equation (1) is to be applied.

The inverse relationship between surface slope and ice thickness predicted by Nye<sup>1,2</sup> has been very useful for estimating the thickness of Pleistocene ice sheets from a knowledge of the position of their margins and their bedrock topography. The findings of this paper do not affect such generalized predictions of ice thickness and volume as they are not sensitive to localized variations of surface slope.

Revision of current thinking is, however, necessary when observed surface slopes are used to predict ice thicknesses. It now appears necessary to use mean surface slopes over distances an order of magnitude greater than  $h$ , except for those regions where curvature is negligible over a distance of order  $h$  as mentioned here. Any attempt to make detailed estimates of bedrock profiles from surface profiles will be complex and can only be justified if one has detailed knowledge of strain rates or of the rates of accumulation and velocities of ice movement over any area studied. The improved theory, however, makes some estimates of ice movement possible on the basis of surface profiles, accumulation and thickness data for regions which are far from fixed reference points on exposed rock.

This paper is based on results of a co-operative programme of field work on the ice sheet of north-west Greenland described briefly by Rinker<sup>17</sup>, and Bailey, Evans and Robin<sup>5</sup>. The work was supported by the US Army Electronics Laboratory, Fort Monmouth, NJ, the US Army Cold Regions Research and Engineering Laboratories, Hanover, NH, and the US Army Research Support Group which provided all logistic support for the work. I thank Dr S. Evans, Mr I. Collins and Dr J. F. Nye for discussion.

# Carbon Isotope Fractionation in the System $\text{CO}_2(\text{gas})-\text{CO}_2(\text{aqueous})-\text{HCO}_3^-(\text{aqueous})$

by

W. G. DEUSER

E. T. DEGENS

Department of Chemistry,  
Woods Hole Oceanographic Institution,  
Woods Hole, Massachusetts

Carbon isotope fractionation between gaseous carbon dioxide and aqueous bicarbonate decreases from 9.2 to 6.8 parts per thousand over the temperature range  $0^\circ-30^\circ\text{C}$ . This fractionation occurs in the hydration stage, not in the passage of atmospheric carbon dioxide through the air-water interface.

It has long been recognized that atmospheric carbon dioxide is depleted in carbon-13 relative to the inorganic carbon pool of the oceans. Reid and Urey<sup>1</sup> were the first to measure the equilibrium fractionation in the exchange  $^{13}\text{CO}_2 + \text{H}^{12}\text{CO}_3^- \rightleftharpoons ^{12}\text{CO}_2 + \text{H}^{13}\text{CO}_3^-$ ; they arrived at a value of  $1.0120 \pm 0.0025$  at  $25^\circ\text{C}$ . Craig<sup>2</sup> found a  $^{13}\text{C}$  depletion of some 7 parts per thousand in atmospheric carbon dioxide relative to oceanic bicarbonate, and Abelson and Hoering<sup>3</sup> redetermined a value of 1.0083 for the fractionation in the foregoing equilibrium at  $25^\circ\text{C}$ . This latter value is apparently the only one derived from laboratory experiments using improved analytical techniques that have become available since the early work of Reid and Urey<sup>1</sup>. No experimental data at all seem to exist on the change of this fractionation over the temperature range  $0^\circ-30^\circ\text{C}$ , yet this is the most important temperature range in the atmosphere and the oceans. Data are also lacking on carbon isotope fractionation between oceanic bicarbonate and molecular carbon dioxide dissolved in the water. Both fractionation effects are of geochemical as well as biological interest. Knowledge of their magnitude may contribute, for example, to an understanding of whether certain marine plants utilize dissolved carbon dioxide or bicarbonate or possibly both species during photosynthesis. We therefore decided to perform several laboratory experiments to determine the size of these fractionations under equilibrium conditions.

Round-bottom, three-neck distilling flasks of 300 ml. capacity were used as reaction vessels. A gas sample tube, a liquid-sampling pipette which consisted of two stopcocks in series with a 3 ml. volume between them, a modified stopcock the bulb of which contained phosphoric acid and a main stopcock for isolating the whole system were attached to the flasks. All stopcocks and joints were lubricated with a minimum of silicone grease in order to avoid contact between solution and grease. The gas sample tube was filled with the desired amount of carbon dioxide and the pipette and the stopcock which contained phosphoric acid were evacuated and closed after the acid was thoroughly degassed. A 50 ml. aliquot of the sample solution was then pipetted into the flask and frozen by placing the flask on a mixture of dry ice and acetone. When the solution was completely frozen the flask was evacuated to a pressure of about  $10^{-3}$  torr and closed. After thawing the solution, the same cycle was repeated so as to remove most of the gases dissolved in the solution. After the second thawing, the carbon dioxide in the gas sample tube was released into the flask and the entire reaction vessel with attachments was immersed in a water bath the temperature of which was controlled to  $\pm 0.5^\circ\text{C}$ . A minimum of 18 h was allowed for equi-

libration during which time the vessel was shaken periodically.

At the end of a run, a portion of the solution was drawn into the pipette for later  $p\text{H}$  measurement and the gaseous carbon dioxide was condensed back into the gas sample tube. Both these steps, and also the  $p\text{H}$  measurement, were carried out at the particular temperature of the experiment. Following the isolation of the gas phase, the solution was acidified by opening and draining the stopcock containing the phosphoric acid. The evolved carbon dioxide was extracted and purified by two passes through a trap cooled with dry ice and acetone. The carbon dioxide constituting the equilibrium gas phase was subjected to the same purification before transfer to the mass spectrometer. The spectrometer used for the isotope ratio measurements is a conventional 6-in.  $60^\circ$  instrument with dual inlet system and double collector, manufactured by Nuclide Corporation.

In the first set of experiments,  $10^{-4}$  mole of carbon dioxide with a  $\delta^{13}\text{C}^*$  of  $-27.0$  parts per thousand was equilibrated with a solution of  $10^{-4}$  mole of sodium bicarbonate with a  $\delta^{13}\text{C}$  of  $-6.0$  parts per thousand. The  $p\text{H}$  of the solution was 8.4, ensuring that roughly 98 per cent of the carbon was present in bicarbonate<sup>4</sup>. The  $\delta^{13}\text{C}$  measured on the carbon dioxide derived by acidifying the solution after the run therefore closely represented the value for the bicarbonate in equilibrium with the carbon dioxide atmosphere above the solution. Fig. 1 shows the data obtained at  $0^\circ$  and  $30^\circ\text{C}$  equilibration temperatures. The reproducibility in all experiments described here is of the order of  $\pm 0.2-0.4$  parts per thousand for  $\Delta$ , that is, the difference between the  $\delta$ -values of the equilibrated phases. As the error in  $\Delta$  depends on two separate sample preparations and analyses in addition to the errors inherent in the equilibration and separation stages, this level of precision seems quite acceptable. Fig. 1 also includes the data obtained in a separate experiment, similar to the one previously mentioned, where the initial carbon dioxide was isotopically heavier ( $\delta^{13}\text{C} = +3.6$  parts per thousand) than the bicarbonate ( $\delta^{13}\text{C} = -6.0$  parts per thousand). This experiment was performed in order to approach equilibrium from the opposite direction. As is evident from Fig. 1, a switchover was achieved and after the run the carbon dioxide above the solution was 9.6 parts per thousand lighter than the bicarbonate. Within

$$^* \delta^{13}\text{C} = \left( \frac{(^{13}\text{C}/^{12}\text{C})_{\text{sample}}}{(^{13}\text{C}/^{12}\text{C})_{\text{standard}}} - 1 \right) \times 1,000$$

All values reported are relative to the Chicago  $P\text{DB}$  standard.

the limitations of these experiments, this value can be considered identical to the others obtained at the same temperature, namely, 9.3, 8.8, 9.1 parts per thousand. The  $^{13}\text{C}/^{12}\text{C}$  difference between atmospheric carbon dioxide and aqueous bicarbonate at  $0^\circ\text{C}$  may thus be taken to be  $9.2 \pm 0.4$  parts per thousand. Table 1 lists the experimentally determined differences and their mean values for  $0^\circ$ ,  $10^\circ$ ,  $20^\circ$  and  $30^\circ\text{C}$ . It also gives the fractionation factors  $\alpha$ , defined as

$$\alpha = \frac{(^{13}\text{C}/^{12}\text{C})_{\text{HCO}_3^-}}{(^{13}\text{C}/^{12}\text{C})_{\text{CO}_2}}$$

for each temperature. These values were calculated from the best fit to all the data in a plot of  $1,000 \ln \alpha$  against  $10^3/T^{-2}$ , where  $T$  is the absolute temperature.

Table 1. EQUILIBRIUM FRACTIONATION OF CARBON ISOTOPES BETWEEN ATMOSPHERIC CARBON DIOXIDE AND AQUEOUS BICARBONATE

Temperature ( $^\circ\text{C}$ )	$\Delta_{\text{CO}_2-\text{HCO}_3^-}$ ( $\text{‰}$ )	$\bar{\Delta}$ ( $\text{‰}$ )	$\alpha$ ( $\pm 0.0003$ )
0	9.3		
0	8.8		
0	9.1	9.2	1.0093
0	9.6		
10	8.1		
10	8.1	8.1	1.0084

20	7.0	7.3	1.0076
30	6.6		
30	7.1	6.8	1.0069

Another series of experiments was aimed at determining the isotopic composition of dissolved carbon dioxide in equilibrium with aqueous bicarbonate and atmospheric carbon dioxide. To this end buffered solutions of pH 6.20–6.53 were allowed to equilibrate with a carbon dioxide gas. The buffers used were mixtures of  $\text{KH}_2\text{PO}_4$  and  $\text{Na}_2\text{HPO}_4$  dissolved in distilled water. The equilibration temperature used was  $0^\circ\text{C}$  in order to maximize fractionation effects. Preparation procedure was identical to the one described previously except that in these runs all the carbon was initially in the form of carbon dioxide gas. On bringing the gas and solution into contact some of the carbon dioxide entered the solution and partly hydrated and dissociated to protons and bicarbonate ions. The molar ratio of free carbon dioxide (this includes roughly 0.1 per cent undissociated  $\text{H}_2\text{CO}_3$ ) to the bicarbonate in the solution is dependent on the pH and the temperature and can be obtained from tables of values calculated by Saruhashi<sup>4</sup>. To determine the isotopic composition of the dissolved carbon dioxide it was then only necessary to measure the pH of the solution at the end of the experiment and the  $\delta^{13}\text{C}$  values of the gaseous carbon dioxide and of the total carbon in the solution ( $\delta\Sigma\text{C(aq)}$ ). The  $\delta^{13}\text{C}$  of the bicarbonate and of the aqueous

carbon dioxide were then calculated from the following equations

$$\delta\text{HCO}_3^- = \delta\text{CO}_2(\text{gas}) + \Delta \quad (1)$$

$$\delta\text{CO}_2(\text{aq}) = \delta\Sigma\text{C(aq)} - Q(\delta\text{HCO}_3^- - \delta\Sigma\text{C(aq)}) \quad (2)$$

where  $\Delta$  is the previously determined difference between the  $\delta$ 's of the carbon dioxide and bicarbonate in equilibrium (9.2 parts per thousand at  $0^\circ\text{C}$ ) and  $Q$  is the molar ratio of bicarbonate ions to carbon dioxide in the solution, a value obtained from Saruhashi's tables for the pH and temperature of the experiment.

Table 2 shows the data obtained in three runs in which  $Q$  varied from 0.41 to 0.89. In all three cases the calculated  $\delta\text{CO}_2(\text{aq})$  is identical to the measured  $\delta\text{CO}_2(\text{gas})$  to within  $\pm 0.5$  parts per thousand or better. Thus the agreement is excellent considering that the errors associated with  $\Delta$ ,  $Q$  and two independent sample preparations and analyses affected the calculation.

Table 2. COMPARISON OF  $\delta^{13}\text{C}$  VALUES ( $\text{‰}$ ) OF  $\text{CO}_2(\text{GAS})$  AND  $\text{CO}_2(\text{AQ})$  IN EQUILIBRIUM AT  $0^\circ\text{C}$

pH	Q	$\delta\Sigma\text{C(aq)}$ (measured)	$\delta\text{CO}_2(\text{gas})$ (measured)	$\delta\text{CO}_2(\text{aq})$ (calculated)	Difference
6.53	0.89	5.7	1.6	1.2	+0.4
6.27	0.48	5.5	2.8	2.4	+0.4
6.20	0.41	5.7	2.7	3.2	-0.5

To obtain a further check on the data presented in Table 2, one additional experiment was performed in which the pH of the solution was lowered to 5.2. At this low pH, 96 per cent of the carbon in solution is in the form of carbon dioxide and the bicarbonate fraction can be neglected for the purposes of the present experiment. In the terms of equation (2),  $Q$  was 0.04, which made the second term negligible and  $\delta\Sigma\text{C(aq)} \approx \delta\text{CO}_2(\text{aq})$ . As the solubility of carbon dioxide at pH 5.2 is appreciably lower than at the pH values of the other experiments the carbon dioxide pressure above the solution was raised by allowing 20 c.c. STP of carbon dioxide to equilibrate with the solution instead of the usual 2.25 c.c. On completion of the run great care was taken not to allow any of the dissolved carbon dioxide to escape the solution. The stopcock of the gas sample tube into which the gaseous carbon dioxide was being frozen was closed as soon as the first bubbles appeared in the solution, produced by the sudden drop in pressure above the solution. It is conservatively estimated that at least 99 per cent of the gaseous carbon dioxide was recovered and that no more than 1 per cent of the dissolved carbon dioxide escaped the solution before the stopcock was closed. The solution was then acidified to liberate the dissolved carbon dioxide. Comparison of the volumes after purification of the gas

Fig. 1. Comparison of  $\delta^{13}\text{C}$  values of carbon dioxide and bicarbonate before and after equilibration at  $0^\circ$  and  $30^\circ\text{C}$ .

samples showed that about 16 per cent of the gas had gone into solution. The initial carbon dioxide of the experiment, comprising the total carbon involved, had a  $\delta^{13}\text{C}$  of  $-27$  parts per thousand. After equilibration the measured values for the gaseous and dissolved carbon dioxide were  $-26.5$  and  $-27.1$  parts per thousand, respectively, which are identical within the established limits of precision.

These experiments have shown that the fractionation of carbon isotopes between atmospheric carbon dioxide and aqueous bicarbonate decreases from  $9.2 \pm 0.4$  parts per thousand at  $0^\circ\text{C}$  to  $6.8 \pm 0.4$  parts per thousand at  $30^\circ\text{C}$  and that there is no measurable fractionation between atmospheric carbon dioxide and carbon dioxide dissolved in water. In the absence of complete stagnancy equilibrium appears to be established rather quickly so that the difference in the kinetics of passage through the air-water interface between the two isotopic species  $^{12}\text{CO}_2$  and  $^{13}\text{CO}_2$  cannot significantly contribute to the carbon dioxide-bicarbonate fractionation. It may be assumed that the fractionation occurs in the hydration step where carbon bonds are rearranged and not in the dissociation although this cannot be ascertained experimentally because of the low relative abundance of the undissociated phase. One biological implication of this is that it is possible to distinguish the inorganic carbon source of aquatic plants. If the plants utilize carbon dioxide only, their carbon should be isotopically identical to that of air breathing plants as long as the utilization proceeds along the same paths and the carbon dioxide can

equilibrate with the atmosphere. If a plant can utilize either carbon dioxide or bicarbonate, depending on their relative availability, the proportion of the two will be reflected in the plant's carbon isotope content. In the extreme case of exclusive bicarbonate uptake, the plant will, depending on mean growth temperature, be 7–9 parts per thousand heavier than in the case of pure carbon dioxide uptake. The apparent ease of equilibration and consequent insignificance of the kinetic effect in the passage of carbon dioxide molecules through the air-water interface also casts doubt on the reality of the large kinetic effect postulated for the passage of carbon dioxide from the atmosphere into the plant cytoplasm during photosynthesis.

In the light of these experiments, carbon isotope differences between most fresh waters (light) and marine waters (heavy) can no longer be interpreted to be exclusively a result of the large biogenic carbon dioxide contributions to rivers and lakes. The pH and consequently the ratio of dissolved carbonic acid derivatives appear to be principal factors in determining the ultimate  $\delta^{13}\text{C}$  in a given water body.

## Isotropic Gamma-ray Intensity in an Expanding Universe

by

CHUNG-CHIEH CHENG

Harvard College Observatory,  
Cambridge,  
Massachusetts

The intensities of isotropic gamma-rays produced by the inverse Compton process in an expanding universe are calculated, including the effect of red-shift on the radiation field. The results may give information concerning the universal black-body radiation field and the intergalactic electron flux intensity.

THIS article presents a calculation of the mean free path and the intensities of isotropic gamma-rays in an expanding universe. Similar calculations<sup>1</sup> have been made, but none has included the effect of the red-shift of the radiation field. We assume, along with Fazio, Stecker and Wright<sup>2</sup>, that the mechanism producing the isotropic gamma-rays is the inverse Compton process that takes place between the high energy cosmic electrons and the assumed black-body radiation field, which is at a temperature of  $3.5^\circ\text{K}$  in the neighbourhood of Earth at the present epoch<sup>3</sup>.

In an isotropic, homogeneous universe, the line element has the familiar Robertson-Walker form

$$ds^2 = c^2 dt^2 - R^2(t) \left[ \frac{dr^2}{1 - kr^2} + r^2 (d\theta^2 + \sin^2 \theta d\varphi^2) \right]$$

We have the relation between  $E_{0\gamma}$ , the energy of the gamma-rays observed at the present epoch  $t_0$  and  $E_\gamma$ , and the energy at the epoch  $t$ , given by the expression

$$E_\gamma = (1 + Z) E_{0\gamma} = E_{0\gamma} \frac{R(t_0)}{R(t)}$$

where  $Z$  is the red-shift. Suppose the cross section of the inverse Compton effect between the black-body radiation field, with a photon density  $n_{\text{ph}}(\epsilon)$ , and cosmic electrons,

with an intensity spectrum  $I_\epsilon = K_\epsilon E_\epsilon^{-\alpha}$ , is  $\sigma(E_\gamma, \epsilon, E_\epsilon)$ , then the gamma-ray source function for the energy  $E$ , produced in a spherical shell at the "time"  $t$ , is given by the equation

$$S(E_\gamma, t) dV(t) = dV(t) \int_{E_\epsilon} I_\epsilon dE_\epsilon \cdot \sigma(E_\gamma, \epsilon, E_\epsilon) \cdot n_{\text{ph}}(\epsilon) d\epsilon$$

where  $dV = -4\pi r^2 R^2(t) dt$  is the volume of the shell. Summing over the contributions from all the shells, we find the intensity of the observed gamma-ray energy,  $E_{0\gamma}$ , at "time"  $t_0$  is

$$I(E_{0\gamma}) = \int_t S \left( E_{0\gamma} \frac{R(t_0)}{R(t)}, t \right) dV(t) / 4\pi D^2(t)$$

where  $D(t) = rR^2(t_0)/R(t)$  is the luminosity distance of the source<sup>4</sup>, and  $E_\gamma$  is replaced by  $E_\gamma = E_{0\gamma} R(t_0)/R(t)$  in the source function  $S$ .

The integral involving the inverse Compton cross section in  $S(E_\gamma, t)$  has been given by Ginzburg and Syrovatskii<sup>5</sup>. We find then that intensity is

$$I(E_{0\gamma}) = -f^1(\alpha) \cdot K_\epsilon \cdot T(t_0)^{\frac{\alpha+5}{2}} E_{0\gamma}^{-\frac{\alpha+1}{2}} c \int_t \left( \frac{R(t)}{R(t_0)} \right)^3 dt$$

where we have used the relation  $T(t)R(t) = T(t_0)R(t_0)$  for the temperature of the radiation field, and  $\alpha$  is the electron flux index. This relation is true so long as the radiation

Table 1.  $Z_c$  AND  $D_I$  AS A FUNCTION OF  $E_{\gamma}$  FOR OPEN AND FLAT UNIVERSES

Observed energy of gamma-rays, $E_{\gamma}$ in eV	$10^4$	$10^5$	$10^6$	$10^{10}$	$10^{14}$	$10^{16}$
$Z_c$ (open)	$7 \times 10^4$	$7 \times 10^3$	$8 \times 10^2$	79	7	0.08
$D_I$ (open, in cm)	$3.2 \times 10^{27}$	$3.2 \times 10^{27}$	$2.15 \times 10^{27}$	$3.15 \times 10^{27}$	$3.1 \times 10^{27}$	Local
$Z_c$ (flat)	$7.4 \times 10^4$	$7.8 \times 10^3$	$8 \times 10^2$	85	8	0.1
$D_I$ (flat, in cm)	$2.7 \times 10^{27}$	$2.7 \times 10^{27}$	$2.7 \times 10^{27}$	$2.65 \times 10^{27}$	$2.65 \times 10^{27}$	Local

field and the matter field have de-coupled, and each undergoes adiabatic cooling independently, as we have assumed in the present calculations. The function  $f^1(\alpha)$  is

$$f^1(\alpha) = f(\alpha) \frac{2}{3} \sigma_T a (mc^2)^{1-\alpha} \left( \frac{4}{3} \times 2.7 k \right)^{\frac{\alpha-3}{2}}$$

where  $f(\alpha) \simeq 1$  for  $\alpha$  in the range 1-2. The integral in the expression for  $I(E_{\gamma})$  is defined as

$$D_I = -c \int_{t_0}^{t=t_c} \left( \frac{R(t)}{R(t_0)} \right)^2 dt$$

and is integrated from the present epoch  $t_0$  to a cut-off "time"  $t_c$ , which is a function of the gamma-ray energy, because different gamma-ray energies have different opacities. This integral can be interpreted as the farthest "distance" we can "see" into the past through each channel of different gamma-ray energies. We now proceed to calculate the mean free paths of the gamma-rays, and hence  $t_c$  and  $D_I$ .

$$\lambda_{\text{open}} = 1.64 \times 10^{19} E_{\gamma} \frac{Z}{1+Z} \left( \exp \left[ -\frac{3.12 \times 10^3}{E_{\gamma}(1+Z)^2} \right] \left( \frac{3.12 \times 10^3}{E_{\gamma}(1+Z)^2} + 1 \right) - \exp \left[ -\frac{3.12 \times 10^3}{E_{\gamma}} \right] \left( \frac{3.12 \times 10^3}{E_{\gamma}} + 1 \right) \right)^{-1} \text{ cm}$$

The most effective absorption of the gamma-rays takes place by pair production, which in our case results from the interaction between the gamma-rays and the cosmic black-body radiation field, which had a higher energy density in the past than in the present. This higher energy density lowers the threshold energy so that the gamma-rays more easily produce the electron-positron pairs, and thus the removal of the gamma-rays is facilitated. The interaction between gamma-rays and cosmic electrons, which is the Compton effect, is about a hundred times less efficient than pair production, and we shall therefore neglect it in calculating the mean free paths.

For gamma-rays traversing a black-body radiation field, which has a photon number density  $n_{\text{ph}}(\epsilon)$  for a distance  $dl(t)$ , we have the differential optical depth  $d\tau(t)$

$$d\tau(t) = dl(t) \int_{\epsilon} n_{\text{ph}}(\epsilon) \sigma(E_{\gamma}, \epsilon) d\epsilon$$

where  $\sigma(E_{\gamma}, \epsilon)$  is the cross section of pair production. Notice that we have neglected the angular dependence of the interaction and assumed that all the interactions are head-on collisions. This will introduce little error, for the gamma-rays and the black-body radiations are isotropically distributed. The cross section of the interaction, which has a maximum value of  $0.7 \pi r_0^2$  ( $r_0 = 2.8 \times 10^{-13}$  cm is the classical radius of the electron) at the black-body photon energy  $\epsilon_{\text{max}} \simeq 2.25 (mc^2)^2/E_{\gamma}$ , is significant in the interval  $\Delta\epsilon \simeq 2\epsilon = 2 (mc^2)^2/E_{\gamma}$  for a given energy  $E_{\gamma}$  of the gamma-ray<sup>6</sup>. The threshold energy relation is  $E_{\gamma}\epsilon = (mc^2)^2$ . We can therefore approximate the cross section as a square pulse of height  $\frac{1}{2} \pi r_0^2$  in the interval  $\Delta\epsilon$ , and zero elsewhere. Using the formula for the black-body radiation photon density,

$$n_{\text{ph}}(\epsilon) = 1/[\pi^2 (c\hbar)^3 (e^{\epsilon/kT} - 1)]$$

we obtain, for an observed gamma-ray energy  $E_{\gamma}$ , the total optical depth from the distance of red-shift  $Z$

$$\begin{aligned} \tau(E_{\gamma}, Z) &= \int_Z \int_{\Delta\epsilon} \frac{c}{H_0} \frac{dZ}{(1+Z)^2 (1+2q_0 Z)^{1/2}} \cdot \frac{1}{\pi^2 (c\hbar)^3} \cdot \left( \frac{1}{e^{\epsilon/kT} - 1} \right) \cdot \frac{1}{2} \pi r_0^2 d\epsilon \\ &\simeq 4 \times 10^{23} \frac{c}{H_0} \cdot \frac{10.12 (mc^2)^6}{E_{\gamma}^3} \int_{Z=0}^Z \frac{1}{(1+Z)^5 (1+2q_0 Z)^{1/2}} \exp \left( -\frac{2.25 (mc^2)^2}{E_{\gamma} kT(t_0) (1+Z)^2} \right) dZ \end{aligned}$$

where we have neglected 1 in the denominator of the Planck function and have used the formula

$$dl = \frac{c}{H_0} \cdot \frac{dZ}{(1+Z)^2 (1+2q_0 Z)^{1/2}} \quad (\text{ref. 7})$$

where  $q_0$  is the cosmological deceleration parameter. This approximation is good as long as we have  $Z \leq 10^7$  for  $E \simeq 10^8$  eV, extending to  $Z \leq 0.01$  for  $E \simeq 10^{15}$  eV, which we shall see is in our range of  $Z$  in the subsequent calculations.

Now defining the mean free path of a gamma-ray photon as

$$\lambda = \frac{Z}{0} \int dl / \tau(E_{\gamma}, Z)$$

we can easily calculate  $\lambda$  by using the expression for  $\tau$  and the formula for  $dl$  as given above. We calculate  $\lambda$  as a function of  $Z$  for an open universe where  $q_0 = 0$ ,  $k = -1$ ; and for a flat universe, where  $q_0 = \frac{1}{2}$ ,  $k = 0$ . Using a value  $H_0 = 100$  km/sec-megaparsec, we have for an open universe

and for a flat universe

$$\begin{aligned} \lambda_{\text{flat}} &= 3.5 \times 10^{15} E_{\gamma}^2 \left[ 1 - \frac{1}{(1+Z)^{3/2}} \right] (1+Z)^{5/2} \\ &\quad \exp \left[ \frac{3.12 \times 10^3}{E_{\gamma}(1+Z)^2} \right] \text{ cm} \end{aligned}$$

From the foregoing formulae we can determine the cut-off red-shift  $Z_c$  by using the condition  $\lambda(Z_c) = l(Z_c)$  for a given observed gamma-ray energy (Fig. 1). In other words, for a given energy the gamma-rays are "visible" to the red-shift  $Z_c$ , beyond which the mean free path of the gamma-ray becomes less than the proper distance from the observer to the source, and hence "invisible". Once we know  $Z_c$ , it is a straightforward matter to calculate the "distance"  $D_I$ . The results for  $Z_c$  and  $D_I$  are shown in Table 1. In the integration of  $D_I$  we have used the relation  $t_c = t_0/(1+Z_c)$  for an open universe, and  $t_c = t_0/(1+Z_c)^{3/2}$  for a flat universe. In Fig. 2 we plotted  $E_0$  against  $Z_c$  for an open universe. It can be seen that the lower the gamma-ray energy, the larger is the cut-off red-shift  $Z_c$ . For gamma-rays of energies greater than  $10^{14}$  eV, the contributions from the distant past of the universe are insignificant, and we can observe only those gamma-rays that originated in our immediate vicinity, that is, our galaxy. This is because of the very high opacity for high energy gamma-rays. Table 1 shows that the distance  $D_I$  changes very little between the lower energies and the energies up to  $10^{14}$  eV, because of the very rapid rise of the cosmic proper distance  $l(Z)$  as a function of  $Z$ , so that  $D_I$  is not sensitive to the change of  $Z$  once  $Z$  becomes greater than unity. The intensities of the gamma-rays can be calculated from the values  $D_I$  and the formula for  $I(E_{\gamma}, Z_c)$ . The value of  $K_e$ , the electron density in intergalactic space, is assumed to be  $10^{-2}$  times

Fig. 1. Optical depth of gamma-rays of observed energy  $E_{0\gamma} = 10^{12}$  eV and the cosmic distance  $l$  are plotted as functions of red-shift  $Z$  for the case of an open universe ( $k = -1$ ,  $q_0 = 0$ ).

that observed in the neighbourhood of the Earth, where the electron flux density is  $K_e = 11 \times 10^{3a-7}$  (MeV) $^a$  (cm $^2$  sec sterad MeV) $^{-1}$ , as given by L'Heureux and Meyer<sup>8</sup>. The results are given in Tables 2 and 3.

In Fig. 3 we plotted the gamma-ray intensity  $I_0$  against the gamma-ray energy  $E_{0\gamma}$ ; also included are the observational spectrum and a theoretical spectrum<sup>2</sup>. The calculated intensity spectrum maintains its slope up to the energy of  $10^{12}$  eV, but is shifted parallel upward from that obtained by Fazio, Stecker and Wright. The parallel shifting of the spectrum without change of slope in an expanding universe has also been pointed out by Felton and Morrison<sup>9</sup>. In our case, this perseverance of the spectrum is due to the large values of  $Z_c$  for  $E_{0\gamma} \leq 10^{12}$  eV and the insensitivity of the cosmic proper distance to large red-shift. The spectrum will not continue to maintain its local shape to very high energy beyond  $E_{0\gamma} \geq 10^{14}$  eV, where, because of the high opacities at these energies, the spectrum will become steeper. The calculated intensities are seen to be in fair agreement with observations in the lower energy range ( $E_{0\gamma}$  approximately  $10^4$  eV), but greater than the observational values by a factor of 100 in the higher energy ranges. Some general conclusions can be drawn from a comparison of theoretical with experimental intensity values.

If we assume that the isotropic gamma-rays are produced throughout the whole universe via the inverse Compton effect between assumed cosmic electrons and the cosmic black-body radiation field, then we get too

Table 2. GAMMA-RAY INTENSITY AT EARTH ( $E_{0\gamma}$ ) IN AN OPEN UNIVERSE (IN PHOTONS/CM $^2$  SEC STERAD MEV)

high a gamma-ray intensity in the neighbourhood of the Earth when compared with the experimental values. This discrepancy can be resolved if we assume an electron flux  $10^{-4}$  smaller than that observed at the Earth, instead of  $10^{-2}$ , as used in the foregoing calculations. Note that we have assumed that the electron flux is constant in time; this may not be true, and it may have been higher in the past than it is now. A greater electron flux would result in a further increase of the gamma-ray intensity. The uncertainty in the electron flux seems to present some difficulties in the extragalactic model.

Apart from the uncertainty of the cosmic electron flux, the high gamma-ray intensities calculated previously suggest some doubt about the existence of a universal black-

Fig. 2. Cut-off red-shift  $Z_c$  plotted as a function of observed gamma-ray energy  $E_{0\gamma}$  for an open universe.

Fig. 3. Intensity spectra of gamma-rays. The calculated spectrum is for an open universe.

body radiation field, if there is a cosmic electron flux greater than  $10^{-4}$  times the flux observed at the Earth. Recently, Daniel and Stephens<sup>10</sup> also raised this doubt, from a comparison of the predicted and the observed cosmic electron spectrum at high energies. Further observations are obviously needed. Finally, the isotropic gamma-rays may not be produced uniformly throughout the whole universe as we suppose here, but may be partially due to unresolved individual gamma-ray sources.

I wish to thank Drs G. G. Fazio and J. Wright for useful discussions.

## Enhancement of Respiration and Fermentation in Algae by Blue Light

by

W. KOWALLIK\*  
H. GAFFRON

Florida State University,  
Institute of Molecular Biophysics,  
Tallahassee, Florida

In the dark, algae live on their reserve substances and respire very slowly. In this state a little blue light can stimulate their dark metabolism considerably. This regulatory effect may be the basis for several responses of plants to blue light.

WHEN micro-organisms run out of food, their respiration continues at the expense of reserve substances, but the rate of this endogenous respiration declines after several hours and finally continues at a fraction of the rate in optimal conditions. This is true for heterotrophs in a mineral environment as well as for photo-autotrophs kept in the dark<sup>1,2</sup>. We have reported that blue light prevents the decline of endogenous respiration in "resting" cells, or, after it has gone down, restores it to a remarkably high value<sup>3</sup>. This effect of blue light was independent of photosynthesis. It still existed when the latter had been abolished either by poisoning with DCMU or by mutation. The effect was found while we were searching for a more immediate metabolic response of algae to blue light than their known peculiar deviation in protein synthesis<sup>4</sup>. We report here on the progress of these investigations.

Most of the experiments were carried out with a mutant of *Chlorella vulgaris* (211-11h/20 of the culture collection of algae at the University of Göttingen) which was free from chlorophyll but contained carotenoids. This organism is most convenient to use because no special precautions are needed to avoid complications with light absorption and light reactions of the chloroplast system.

As Fig. 1 shows, the effect of blue light on the uptake of oxygen by this yellow mutant could be easily seen either with the Warburg manometric technique or with an "oxygen sensor". In the latter case the current between a gold cathode and a silver anode changes in proportion to the partial pressure of oxygen in the suspension of algae. Depending on the degree of starvation, blue light enhanced the rate of the endogenous respiration up to five times, and maintained it at such a rate for a day or longer. In one experiment, which lasted 41 h, the enhanced respiration began to decline markedly after 20 h of uninterrupted illumination. The relative rates after 2 h were dark 15, blue 29; after 21 h they were dark 4, blue 21; and after 41 h they were dark 2, blue 13. We have seen no case where the induced rate surpassed the maximal rate of respiration in the presence of sufficient exogenous glucose or acetate, or a rate stimulated by optimal concentrations

of dinitrophenol. To obtain good effects, the glucose grown algae were therefore starved for a day or two in plain buffer before the experiments.

The extra oxygen consumption in blue light was a true respiration. Its respiratory quotient was approximately unity and did not change with the increase in rate; that is the release of carbon dioxide followed exactly the increase in oxygen uptake. The temperature dependence of the slow respiration in the dark and that of the fast, light induced respiration was the same. The blue light effect was perfectly reversible. Between 15 and 30 min after "light off" the respiration was almost back to its normal dark level. Such "on" and "off" tests could be repeated many times.

Fig. 1. Acceleration of endogenous respiration by blue light in the yellow *Chlorella* mutant 211-11h/20 suspended in 0.1 molar phosphate buffer, pH 6.5, at 30° C. (a) Oxygen uptake measured manometrically. Light: broad band  $\lambda > 366 - < 550$  m $\mu$ ,  $\sim 3 \times 10^3$  ergs sec<sup>-1</sup> cm<sup>-2</sup>; 70  $\mu$ l. of packed cells  $\sim 15$ -5 mg dry weight/vessel. (b) Oxygen uptake as recorded with an "oxygen sensor". Light:  $\lambda$  450 m $\mu$  interference filter 9 m $\mu$  halfwidth.  $\sim 500$  ergs sec<sup>-1</sup> cm<sup>-2</sup>.

\* Present address: 2 Botanisches Institut, 5 Köln-Lindenthal, Weyertal 121, Germany.

So far we have found conspicuous differences between the normal and the light induced respiration in the respective responses to the nature and the pH of the suspension medium. The endogenous respiration was markedly slower in 0.1 molar phosphate buffer than in 0.1 molar bicarbonate both at pH 8.5, and also slower in phosphate at pH 6.5 than at pH 8.5. The enhanced respiration in blue light, however, showed virtually no influence of either pH or bicarbonate versus phosphate—the rates remained equally fast<sup>5</sup>. Consequently, the difference between the uptake of oxygen in the dark and that in the light was the more impressive the slower the rate of the former.

In contrast to photosynthesis and more like photoperiodism and phototropism, the amount of light needed to give a measurable enhancement of oxygen uptake in the conditions of our experiments was quite small. At  $\lambda$  450 m $\mu$  50 ergs cm<sup>-2</sup> sec<sup>-1</sup> sufficed for half-saturation, and 500 ergs cm<sup>-2</sup> sec<sup>-1</sup> for complete saturation of the blue light effect, while photosynthesis with blue light in green plants needs from 10,000–50,000 ergs cm<sup>-2</sup> sec<sup>-1</sup>.

An action spectrum for the enhancement of respiration has been determined by Kowallik<sup>6</sup> using the oxygen sensor technique. Far-red, red and yellow light were completely ineffective even at ten times the intensity which was sufficient to saturate the effect in blue light. The maximum activity for equal flux of incident quanta was found in a broad peak around  $\lambda$  460 m $\mu$ . The efficiency dropped steeply towards the green with no activity beyond  $\lambda$  520 m $\mu$  and towards the ultra-violet, but there a second, smaller peak appeared around  $\lambda$  375 m $\mu$ . This action spectrum is almost identical with that for the phototropic responses of *Phycomyces* sporangiothecae<sup>7</sup> and of *Avena coleoptiles*<sup>8</sup>, for carotenoid formation in *Fusarium*<sup>9</sup> and

for the retardation of flower opening in *Oenothera*<sup>10</sup>. Rau believes that his action spectrum indicates the function of a flavin. The other authors independently agree that these action spectra do not show whether the active pigment is a flavin or a *cis*-carotenoid.

Flavin is a part of the respiratory chain and so the question arose as to whether the effect of blue light on respiration was directly on the oxidative electron transport chain. If this was so the effect might disappear in anaerobic conditions. Furthermore, a direct photochemical influence on the respiratory mechanism should become apparent immediately after exposure to blue light. This, however, was not the case. In dozens of experiments of the type shown in Fig. 1, it took between 10 and 20 min from "light on" until the new steady rate of gas exchange was reached. And this was similarly true, as already mentioned, for the return to the dark rate after "light off". These transient periods were therefore much longer than those in photosynthesis. Obviously some slow and complex metabolic reaction preceded the visible increase in respiration. Further experiments in the absence of oxygen confirmed this.

If algae in phosphate buffer of pH 5.0 were kept anaerobically in darkness or blue light only a small positive gas pressure change could be seen. There was, however, a measurable pH change in the medium. This fits the well known observation that fermenting green algae and their mutants chiefly produce acids, little free carbon dioxide. The amount and the kind of such fermentation end-products may vary considerably among different species and depend largely on culture conditions<sup>11</sup>. Which acids are formed in our case we may leave aside for the moment.

Under nitrogen the pH of a suspension of the yellow *Chlorella* mutant in 0.002 molar phosphate buffer changed in the dark from 6.45 to 6.38; in blue light, however, to 6.29 in 50 min. This light-enhanced production of acids in anaerobiosis could also be demonstrated with 0.01 molar sodium bicarbonate as suspension medium: in blue light about nine times more carbon dioxide was released from the bicarbonate by the acids produced than in darkness. Blue light thus increased fermentation by this *Chlorella* mutant in these conditions.

Further proof that blue light is responsible for the release of more fermentation products when algae are incubated anaerobically is given in Fig. 2. Four equal samples of algae were kept under nitrogen for 140 min. One was left in the dark during the entire period, and the others were illuminated for 10, 30 or 60 min immediately before being brought back into aerobic conditions. In all four samples the ensuing respiration in the dark was greater than before. But the rate of oxygen uptake in the samples which were exposed to light under nitrogen was faster than that of the dark control. The difference between the amounts of oxygen consumed by the dark control and the samples exposed to blue light was proportional to the time of illumination (see Table 1). In the absence of oxygen blue light had produced something which served afterwards as substrate for respiration in the dark. In these circumstances the enhanced respiration started without an induction period at its highest rate, and, as usual, declined in the course of time. Further experiments showed that the substances made available to the respiratory system by anaerobic pre-treatment with blue light were very stable. It made no difference whether air was re-admitted afterwards in the dark immediately or 1 or 2 h later.

The anaerobic metabolism enhanced by blue light had a pronounced dependence on temper-

Fig. 2. Enhancement of dark respiration in a yellow *Chlorella* mutant after an anaerobic incubation period during which one sample remained dark, the others were exposed for 10, 30 or 60 min respectively to blue light. 300  $\mu$ l. of packed cells in 3 ml. of 0.1 molar phosphate buffer, pH 6.5, at 30–4° C.

ature. In the experiment shown in Fig. 3 the organisms were first exposed to light in anaerobic conditions at a temperature of 0° C instead of 30° C. When they were afterwards tested aerobically at 30° C in the dark the usual difference in respiratory rates between unilluminated and samples exposed to blue light did not show up. This experiment shows that no primary products are formed which live long enough to influence the metabolism some time later. We conclude that the blue light establishes or regulates conditions which permit a normal endogenous metabolism to proceed faster while the light is on.

Reports of the influence of light on respiration date back to the second half of the nineteenth century. The vast literature which has accumulated since that time is full of contradictory statements, even concerning the same type of experiment with the same living object (for literature review see ref. 12). If we restrict our discussion to earlier results which showed a positive light effect on the respiration of plants, we may eliminate from this group all enhancements obviously caused by recent photosynthetic production of new carbon compounds. Among the remaining ones we may ignore a stimulation of oxygen uptake as the consequence of injury by ultra-violet radiation or effects attributed specifically to far-red light.

Thus we are left with very few experiments which indicate an effect of blue light exclusively on respiration<sup>13-15</sup>.

One of the clearest earlier observations is that of Emerson and Lewis<sup>14</sup>. While trying to determine the right correction for respiration in their measurements of the quantum efficiency of photosynthesis at different wavelengths, they observed that the oxygen consumption in the dark had increased after illumination with blue light at  $\lambda$  480 m $\mu$ , but not after illumination with light at  $\lambda$  435 or 560 m $\mu$ . They also saw that during the light periods photosynthesis increased slowly in blue-violet or yellow light, but decreased in the blue. The authors concluded "that the alteration in rate of pressure change during the early part of the (blue) light period was due to an increase in respiration rather than a decrease in photosynthesis", and wrote further "a strictly photochemical effect of this kind would not be expected to carry over into the ensuing dark period, nor should it be so slow in starting". Very likely 24 yr ago Emerson and Lewis came across the same phenomenon we have been watching directly in the absence of a photosynthetic activity. The reason why their findings were never followed up was probably the difficulty of reproducing them.

This brings us to the fact that our effect of blue light was most pronounced in very peculiar conditions. The farther removed they were from those considered optimal for the life of the cell, without actually being harmful, the easier it was to find the difference between metabolic rates in darkness and in weak blue light. One cannot readily see what advantage should accrue to a resting cell by being stimulated into using up its reserves when it has no further means of subsistence. The true usefulness of the blue light must be to serve as a regulating factor in circumstances where this regulation cannot readily be observed. This regulation of respiration by blue light does not seem to occur universally. So far we did not see an effect in *Rhodotorula*, *Prototheca*, and in some blue green algae, while we found it in several strains of green and red algae.

Besides those cases mentioned here, where virtually identical action spectra bespeak metabolic relationships<sup>6-10</sup>,

Table 1. PROPORTIONALITY BETWEEN TIME OF BLUE LIGHT TREATMENT IN NITROGEN AND SUBSEQUENT EXTRA OXYGEN UPTAKE IN AIR IN THE DARK				
Time (min) of light exposure in nitrogen	10	30	60	
Excess $\mu$ l. of oxygen absorbed	30 min	6	14	33
in darkness after:	60 min	10	35	62

Fig. 3. Comparison between the oxygen uptake at 30° C in darkness by algae which had been in the dark or exposed to blue light under nitrogen at 0° and at 30° C. ~300  $\mu$ l. of packed cells of yellow *Chlorella* mutant 211-114/20 suspended in 0.1 molar phosphate buffer at pH 6.5.

we should mention the following observations where the blue light effect we have described might be involved. Clauss<sup>16</sup> found that *Acetabularia* would eventually stop growing in pure red light, and Terborgh<sup>17</sup> adduces evidence that this had its counterpart in a decline of photosynthetic capacity. The addition of a little blue light overcame the inhibition of photosynthesis in Terborgh's experiments, and that of growth in those of Clauss. A similar claim for the need of traces of blue light in the photosynthesis of *Chlorella* was put forward some years ago by Warburg *et al.*<sup>18</sup> (but see the analysis of this paper by Kok<sup>19</sup>).

Considering the mechanism of the blue light effect, it seems fairly certain that it does not act directly on respiration or on fermentation, but rather on the release of some carbohydrate by surprisingly small amounts of light. Thus we might consider changes in permeability or in phosphorylation or both. The next experimental attack ought to be on the nature and the site of the pigment, the nature of the substance released and the primary photochemistry.

# Nature of the Scrapie Agent

There is evidence to suggest that the infectious disease scrapie is caused by an agent which does not depend on a nucleic acid for its ability to replicate. In the first of the two following articles it is suggested that scrapie can best be considered to arise from a replicable change in the structural pattern of a commonly occurring unit membrane. In the second article it is suggested that the agent is a protein and three possible mechanisms for its self-replication are proposed.

DESPITE the fact that the agent of scrapie has some unusual properties, it has been usual to consider it a member of the class of "filter-passing viruses"<sup>1</sup>. This class of agent, however, has been defined structurally by Wildy and Watson<sup>2</sup> and according to current conception it should always contain nucleic acid. The recent experiments of Alper *et al.*<sup>3</sup> have clearly shown that the agent of scrapie is much more resistant to the action of ionizing and ultra-violet radiation than any known viral agent, and these authors have suggested that the agent of scrapie probably contains no nucleic acid at all.

Even before these remarkable observations were published, it had become evident that the agent of scrapie was somewhat exceptional, and indeed the viral nature of the agent had been questioned at an earlier stage<sup>4</sup>. A summary is given in Table 1 of the behaviour of the agent towards chemical reagents and under a variety of physical conditions. Quantitative information has been obtained from studies with a form of the agent that has been adapted to mice<sup>5</sup>, because only in the mouse (and possibly in the rat or hamster) is it routinely practicable to carry out titration experiments. A cursory examination of Table 1 shows that, for a self-replicating agent, scrapie has rather bizarre properties. There are substantial difficulties in identifying the agent as a virus, a nucleic acid, a protein or a polysaccharide, and we suggest here that the presence of the agent of scrapie in a cell may represent an alteration in the basic three-dimensional configuration of a commonly occurring unit membrane structure. Such an alteration would not necessarily require the introduction of any new molecular components into the cell affected by scrapie.

In a field such as this, speculation is easier to come by than good experimental data. Nevertheless, it is perhaps useful at this stage to assemble the existing information, including some recent unpublished results, relevant to the chemical nature of the scrapie agent.

(1) *Virus hypothesis.* It is still possible to make out a case that the agent of scrapie is a virus: scrapie disease is caused by a filtrable and transmissible agent<sup>1</sup> and in some respects exhibits the typical development of a neurotropic virus multiplying at an unusually slow rate<sup>17</sup>. The agent of scrapie is unusually resistant to formalin. It should be borne in mind, however, that twin-stranded nucleic acid molecules react very slowly with formaldehyde and that polyoma virus is relatively resistant to the action of this chemical<sup>18</sup>. To explain the behaviour of the agent of scrapie, it is only necessary either that it should readily release its nucleic acid, or that its outer surface should be unusually resistant to the action of formalin, as are some protein and many carbohydrate molecules.

Attempts to isolate or to visualize the scrapie agent have failed to provide support for the virus hypothesis. Similarly, a detailed investigation<sup>19</sup> of nucleic acid metabolism in scrapie brain has not revealed the presence of a nucleic acid specific to scrapie. The strongest evidence against the virus hypothesis comes, however, from the experiments on ultra-violet irradiation. It is difficult to dismiss these, and the simple explanation that the scrapie

agent contains no nucleic acid is probably correct, especially as the results obtained from the use of ionizing radiation suggest that if it is a virus then it is unusually small. Two principal possibilities remain, however, both of which would be consistent with a viral-type agent. (i) There may be an unusually active nucleic acid repair system operating in brain. (ii) The agent may contain a nucleic acid of unusually simple sequence, such that small sections of the polynucleotide chain retain the full informational sequence of the agent.

While neither of these suggestions seems very plausible, they are certainly not impossible and, in view of the difficulties inherent in the assignment of an informational role to any other type of molecule, the virus hypothesis cannot be entirely dismissed.

(2) *Protein hypothesis.* Crick<sup>20</sup> has considered the problem of whether a protein can carry genetic information and considers it intrinsically improbable. Nevertheless, as he points out, it is not impossible to construct hypotheses whereby a protein could provide genetic information within the framework of modern molecular biology. No such situation is known to exist. Proteins vary considerably in the degree of their resistance to physical and chemical agents and many of the results listed in Table 1 would be consistent with a protein character for the agent of scrapie. One would certainly not expect, however, a

Table 1. RESPONSE OF THE AGENT OF SCRAPIE TO VARIOUS PHYSICAL AND CHEMICAL TREATMENTS

Treatment	Effect	References
Ionizing radiation	$D_0 = 4.3$ Mrads	3
Ultra-violet radiation at 240, 254, 265, 280, 290, 315 and 330 m $\mu$	Negligible loss of titre with incident doses up to $5 \times 10^4$ ergs/mm <sup>2</sup>	3
Heat at 100° C for 10-60 min	Substantial, but incomplete loss of titre	6, 7
Heat at 80° C for 60 min	Negligible loss of titre	6, 7
Treatment with fluorocarbon at 0°-4° C	Negligible loss of titre	8
Heat at 80° C for 20 min after fluorocarbon treatment	Substantial loss of titre	9
Treatment with ether at room temperature	Partial loss of titre	10, 11, 12
Acid and alkali	Essentially stable in pH range 2.5-10.5. Destroyed by strong acid and alkali	11, 13, 14
Formalin, 0.5-18 per cent	Highly resistant. Some loss of titre, but no accurate quantitative data available	4, 15
$\beta$ -Propionolactone, 1 per cent	Slight loss of titre	14
0.01 molar periodate at pH 4 at room temperature	Substantial loss of titre	9
6 molar or 8 molar urea	Substantial loss of titre	7, 9
90 per cent phenol	Substantial loss of titre	7, 9
Strong salt solutions (for example, 6 molar lithium chloride, caesium chloride and ammonium sulphate)	Titre readily lost under various conditions	8, 13
Detergents	Relatively stable in the presence of neutral detergents and 0.01 molar sodium deoxycholate	6, 8
Proteolytic enzymes	Partial loss of titre after fluorocarbon treatment, but very little before it	8, 9, 11
DNase, RNase, lipase, phospholipase $\alpha$ , phospholipase $\epsilon$ , neuraminidase, $\beta$ -glucuronidase	No effect on titre of crude preparations	7, 8, 16

protein sensitive to the action of strong solutions of urea and phenol to show such a marked resistance to the action of heat and formalin; nor would most proteins be so sensitive to the action of periodate under the conditions applied to the agent of scrapie<sup>21</sup>. Treatment with proteolytic enzymes would be expected to produce more marked effects than have been observed if the agent were a simple protein.

Only proteins with rather special amino-acid composition would exhibit the observed degree of resistance to ultra-violet light at certain wavelengths and, furthermore, unlike the agent of scrapie<sup>22</sup>, most proteins of a size indicated by the degree of sensitivity to ionizing radiation would be highly antigenic. Basic nucleoproteins, however, are usually deficient in aromatic amino-acids and are also poor antigens and they are in intimate contact with gene DNA. There is evidence that they are concerned in gene expression<sup>23</sup>. The activation by nucleohistone of a gene responsible for its own synthesis has not been reported but, nevertheless, if the nucleic acid hypothesis must be abandoned, nucleohistone is perhaps one of the most likely substances to fulfil a self-replicating role. The agent of allergic encephalomyelitis is certainly a basic polypeptide, and some workers have pointed out resemblances between this agent and that of scrapie<sup>24,25</sup>.

(3) *Carbohydrate hypothesis*. The biosynthesis of polysaccharide, glycoprotein and protein-polysaccharide complexes follows a course quite distinct from that of protein synthesis. These substances are apparently constructed by the transfer of sugars or small oligosaccharide units (frequently by way of a phospholipid intermediate<sup>26</sup>) from an appropriate sugar nucleotide to an acceptor molecule. The acceptor site will usually be a free hydroxyl group of a sugar in a pre-existing poly- or oligo-saccharide chain. With polysaccharides there is provision for the initiation of synthesis and, with protein-polysaccharide complexes and glycoprotein, transferases which will use an amino-acid residue (serine, threonine or asparagine) as acceptor. It is the synthesis of the sugar transferring enzymes that is under direct genetic control, rather than the synthesis of oligosaccharide or polysaccharide<sup>26-28</sup>.

The hypothesis was therefore formulated that a foreign oligosaccharide or polysaccharide or glycoprotein may induce the synthesis of polysaccharase which would also be able to function as a transferase; in this way a polysaccharide or oligosaccharide would appear to be self-replicating. While it is true that the synthetic activity in, for example, induced disaccharases has not yet been demonstrated, it is clear that, if the agent of scrapie is devoid of nucleic acid, some such novel process which results in apparent self-replication must exist. Increases in the activity of three carbohydrases in scrapie brain have in fact been reported<sup>29</sup>. Suggestions that the agent of scrapie may contain carbohydrate<sup>29,30</sup> can in this way be provided with a theoretical basis and other related hypothetical schemes can be constructed.

The experiment in which a scrapie preparation was oxidized by periodate<sup>9</sup> was designed as a partial test of this hypothesis and indeed the agent of scrapie is labile to this mild and rather specific glycol-cleaving agent. Polysaccharides and oligosaccharides are rather stable substances and resist treatment with formaldehyde and ultra-violet light. We must conclude, however, that scrapie cannot be caused by a simple oligosaccharide or polysaccharide, because if it were it would surely survive treatment with phenol and strong urea—reagents widely used in the isolation of polysaccharides.

(4) *Membrane hypothesis*. Another approach to the problem is to fractionate tissue infected with scrapie and to determine whether activity is associated with any particular organelle or class of biochemical substances. This approach has been singularly unfruitful, and all fractions obtained by differential centrifugation techniques are infective<sup>31</sup>, even the final cell sap supernatant,

although this can be largely cleared of activity by prolonged ultra-centrifugation. It is possible to remove the bulk of the brain lipids without much loss of activity<sup>9,13</sup> and it is easy to produce partially cleared suspensions containing small amounts of activity after shaking the ground tissue with a variety of aqueous solutions<sup>8</sup>. This can be done continuously, and even after fifty such "extractions" further small quantities of activity can be removed from the coarser debris by shaking with water or saline<sup>28</sup>. Attempts to dissociate completely the activity from tissue debris using detergents, enzymes, solvents and chromatographic techniques have been unsuccessful<sup>6,8</sup>, however, and one is forced to conclude that there is an extremely tenacious association of the agent with almost every type of cell component. But there is one part of the cell which is often ignored but which does behave in the manner observed, that is cell membrane.

Known membrane constituents, for example the mouse histocompatibility antigens<sup>32</sup>, do behave on fractionation or extraction of tissue components in much the same way as does the agent of scrapie, although some of these antigens differ markedly from scrapie in their overall stability. The membrane appears to break up into fragments of greatly varying sizes which contaminate all the subcellular fractions. The idea that the infective agent may be part of the structure of the cell membrane is at least worth further examination and could well account for conflicting observations of the size of the agent<sup>11,33</sup>. In their simplest form, cell membranes appear in electron micrographs as double-layered structures the components of which are protein and phospholipid<sup>34</sup>. The membrane is not a uniform structure; there are regions responsible for the active transport of ions and other substances into and out of the cell. Specific antigenic substances are also located on the membrane and in the most thoroughly investigated cells (the erythrocyte and the Ehrlich ascites tumour cell) sugars are prominent among these antigenic determinants<sup>35</sup>. Neuraminic acid has also been associated with an active transport site<sup>36</sup>, and an isolated histocompatibility antigen<sup>37</sup> has been found to possess enzyme activity suggestive of the behaviour of ion transport systems. Although the activities can be separated, antigenic and transport sites may be functionally related.

If the determining factor in scrapie pathogenesis is a steric arrangement of the membrane—and we specifically suggest that it is likely to be a re-arrangement in the sugar or oligosaccharide residues attached to it—then the agent of scrapie would behave, when subjected to the chemical and physical treatments listed in Table 1, in the very curious ways observed. Membranes are usually rather resistant to the action of proteolytic enzymes and heat, presumably as a result of the protection afforded by the lipid layers. These phospholipid layers would be disturbed and perhaps partially removed together with the bulk of the neutral lipid by emulsification with fluorocarbon. While the protein would probably react with formaldehyde, provided the membrane fragment was not lysed, the steric arrangement in anything attached to it would be preserved. Because solutions of urea and phenol are potent breakers of hydrogen bonds, however, they will disperse and solubilize the membrane and destroy its specific molecular arrangement.

There are some additional more speculative points concerning the replication and pathogenicity of the agent which are perhaps worth noting. One may take advantage of our ignorance of the way in which membrane is synthesized to suggest that it may in fact be produced by a self-copying process not directly involving nuclear DNA, and that a foreign membrane fragment may become incorporated and later copied. Studies on one highly developed living cell, *Paramecium*, suggest that precisely such a process can occur<sup>38</sup>. Alternatively, the suggestion put forward for the self-replication of polysaccharide is equally applicable to an oligosaccharide on the surface of a membrane. Turning to the pathogenicity of the agent,

it should be pointed out that no antibody against scrapie has yet been detected, and the agent seems to multiply in tissues outside the nervous system<sup>17</sup> without causing obvious damage. There are, however, indications of association between sugars on the cell surface and ion transporting systems and, while cells of all tissues possess such systems, the ion transport system in nerve cells is extremely specialized, sensitive and rapid. Tentatively, then, it is suggested that the alteration in the arrangement of sugars attached to the membrane causes some impairment in the efficiency of ion transport, but is insufficient to be immunologically recognizable. Some alteration in the degree of antigenicity might nevertheless be expected and has in fact been observed<sup>22</sup>. Such a slight change in membrane structure as that postulated may be disastrous only in central nervous tissue.

These conclusions, based on a study of scrapie disease, may have implications for workers in the field of human nervous disease, other slow virus infections and cancer research. The interested reader is referred to the excellent short review article recently published by Gajdusek<sup>23</sup>.

We thank Dr W. S. Gordon for his interest in this work, and Dr R. H. Kimberlin, Mr G. C. Millson and Dr D. L. Mould for valuable discussions. The work has been supported in part by grants made to the Agricultural Research Council under US Public Law 480.

## Self-replication and Scrapie

It has been suggested that the agent responsible for scrapie, which affects sheep, has a very low molecular weight ( $\sim 2 \times 10^5$ ) and is probably a protein without nucleic acid<sup>1,2</sup>. It can infect goats, rats, mice or hamsters as well as sheep<sup>3,4</sup>. This behaviour would not have been surprising had scrapie contained DNA or RNA because any cell contains the machinery to copy arbitrary sequences of nucleotides. It is not generally thought, however, that they can copy polypeptides and the idea that scrapie is a protein therefore presents difficulties. In this article I discuss the self-replication of proteins and argue that there are at least three distinct kinds of way in which it could occur. This shows that there is no reason to fear that the existence of a protein agent would cause the whole theoretical structure of molecular biology to come tumbling down.

**The First Way.** It is generally supposed that a large number of the genes of a mammalian cell—differentiated or otherwise—are switched off by the action of repressors. It is possible that, through a chance mutation, a gene *G* may arise which is switched off in all cells of a particular animal. If this mutation is not selectively disadvantageous, it will simply persist. Suppose, furthermore, that *G* codes for a protein *S* which acts as an inducer for *G*. Then *S* could act as an infective agent because it is normally never present but, if it is introduced, it will reproduce itself.

We now consider various properties of scrapie on the hypothesis that it is such an *S*. The infectivity of scrapie depends on the rate at which it is induced in a given cell and the rates at which it leaks out through the cell membrane and in through other membranes. In the light of this, we would not be able to predict the long period of induction (months-years)<sup>5</sup> but we would not be surprised by it.

A considerable range of sensitivity and clinical symptoms is observed in sheep and two distinct limiting forms of the disease have been recognized<sup>6</sup>. These breed practically true in the goat<sup>6</sup> but probably do not in the sheep<sup>5</sup> and these facts introduce a curious complexity into the picture. We shall consider first the difference in sensitivity between individual sheep.

Because the protein *S* is never normally formed, further mutations of *G* itself can occur harmlessly. Some sheep might therefore code for an *S* which acts as an inducer and some for an *S* which does not. So far as cells within a given sheep are concerned, a difference in sensitivity might reflect either a difference in the damage done by the presence of *S* (which may be enzymatically active) or in the degree of repression of *G*.

The fact that other animals are also susceptible to scrapie may seem to imply that they contain identically the same gene *G*. This is not the case and all that is necessary is that the protein *S* (from, for example, a sheep) should induce a gene *G*<sup>1</sup> (in, for example, a goat) with similar properties to *G*. A common hereditary origin for *G* and *G*<sup>1</sup> is, however, suggested because the protein *S*<sup>1</sup> from *G*<sup>1</sup> can infect the sheep, that is, act as an inducer for *G*.

The occurrence of two distinct forms of the disease would seem to imply, on the present hypothesis, two genes *G*<sub>1</sub> and *G*<sub>2</sub> with corresponding *S*<sub>1</sub> and *S*<sub>2</sub>. In some cases *S*<sub>1</sub> could induce *G*<sub>2</sub>, and vice versa, and in some cases not.

There is some evidence that scrapie can arise spontaneously<sup>7</sup>. If so, we would interpret it by saying that *G*

is not repressed with absolute efficiency and so, even in a healthy animal, a molecule of S may occasionally be found.

The hypothesis is very similar to one of the suggestions made by Monod and Jacob about the mechanism of differentiation<sup>8</sup>. As in that case, it is certainly not the only possible one. For example, S could be an enzyme which catalyses the formation of a metabolite M, which is the inducer and not present in normal cells. If so, M as well as S would act as an infective agent, which does not seem consistent with the closely exponential radiation inactivation curve found by Alper, Haig and Clarke<sup>2</sup>. Then, again, any set of proteins would do provided the individual proteins are never produced simultaneously in any normal cell and that collectively they induce their own production. For example, it is easy to produce a model based on two proteins P<sub>1</sub> and P<sub>2</sub> such that each of P<sub>1</sub> and P<sub>2</sub> occurs separately in some normal cell and scrapie is P<sub>1</sub> and P<sub>2</sub> occurring together.

**The Second Way.** Self-replication need not involve any very intricate mechanism, provided that suitable components are available<sup>9</sup>. Penrose and Penrose illustrated this with a mechanical example<sup>10</sup> but we shall now see that a logically similar one could be made out of protein.

Given protein sub-units  $\alpha$  which can undergo the following reactions

it is clear that the net result is that the monomer  $\alpha$  gets converted into the dimer  $\alpha_2$ . If we suppose also that the reaction

cannot take place directly, it follows that  $\alpha$  can only dimerize to  $\alpha_2$  under the catalytic influence of molecules of  $\alpha_2$  which are already present.

Next we show that this reaction scheme could be realized through the assignment of physically reasonable properties to the protein sub-units. Let the reactive sub-unit  $\alpha$  be a different conformation of the stable structure,  $\alpha'$ , say, of the protein. Then we have the equilibrium

The free energy change  $\Delta F_1$  could easily be so large (for example,  $>100$  kT) that the mean total number of sub-units in all cells in the animal, which are in the form  $\alpha$ , is much smaller than unity. We suppose, then, that all sub-units are in the conformation  $\alpha'$ . The reaction

may then be very favourable to the formation of dimers but can never proceed because no molecules in the conformation  $\alpha$  are available. In fact if  $\Delta F_2 > 2\Delta F_1$ , the reaction

is thermodynamically favourable to  $\alpha_2$  but cannot actually proceed. (I mean by this, strictly, that it will be an enormously long time before even a single molecule of  $\alpha_2$  appears.)

The remaining reactions are

with  $\Delta F_3 > 0$ ,  $\Delta F_4 > 0$ ,  $\Delta F_5 > 0$ . The first two reactions of equations (6) involve the combined combination of  $\alpha'$  and change of its conformation. That this, unlike reaction (5), should proceed at measurable velocity is quite plausible because  $\alpha'$  can fold into its new conformation as it joins onto the "template"  $\alpha_2$  or  $\alpha_3$ . Finally, we can combine equations (5) and (6) to show that

$$\Delta F_5 = -2\Delta F_1 + \Delta F_2 - \Delta F_3 - \Delta F_4 > 0 \quad (7)$$

which is true if both  $\Delta F_3$  and  $\Delta F_4$  are small. The first of these conditions requires no justification. The second could be interpreted to mean that the tetramer  $\alpha_4$  is very

strained, the strain energy thus offsetting the energy of linkage between  $\alpha$  and  $\alpha_3$ .

Assuming that  $\alpha'$ , but not  $\alpha$  or  $\alpha_2$ , is a normal cellular constituent and that  $\alpha_2$  can penetrate the cell wall, then  $\alpha_2$  will act as an infective agent made of protein. With such an explanation of scrapie, it would be easy to understand the spontaneous appearance of the disease in previously unaffected animals: it could mean that the equilibrium (3) is not quite so unfavourable to the formation of  $\alpha$  as we have supposed. The existence of the two clinically distinct forms of scrapie could be explained if there were two similar (perhaps isozymic) sub-units  $\alpha'$  and  $\beta'$ , each satisfying similar reaction schemes and in some cases (for example, in sheep) being able to form mixed polymers such as  $\alpha_2\beta$  and in some cases not (for example, in goat).

Just as with the first way, more complicated reaction schemes along the same lines are possible. There is an obvious analogy between the idea presented here and the idea that a gas can only condense on nuclei which are already present: many of the more general schemes could be summed up by saying that the sub-units can only polymerize by utilizing "condensation nuclei" of polymer which are already there.

**The Third Way.** In the first two ways the infective agent used the products of a single cell to replicate itself. In the third way it uses apparatus belonging to the whole animal. To the animal, a foreign protein often acts as an antigen (A) which stimulates the production of an antibody (A'). A' is a protein which is normally different from A. It could happen that there exists an A for which A' = A. This gives our third way. The mechanism of production of antibodies is not understood in detail but there seems no reason to expect it to be inexplicable in terms of the ideas of present day molecular biology<sup>11</sup>. Thus the same would be true of an infective agent using the third way. It should be pointed out that this is not an "auto-immune" mechanism. Immunologists mean by that term that the animal makes antibodies against its own tissue constituents, not that the antibodies are chemically identical with the antigens. It seems probable, however, that scrapie does not use the third way because there is good experimental evidence that the disease is not antigenic<sup>12</sup>.

I have shown the existence of at least three classes of replication mechanisms and that, therefore, the occurrence of a protein agent would not necessarily be embarrassing although it would be most interesting. There is evidence that scrapie does not belong to the third of these classes. If it belongs to one of the first two classes, then it is a protein or a set of proteins which the animal is genetically equipped to make, but which it either does not normally make or does not make in that form. It may be passed between animals but be actually a different protein in different species. Finally, in either case, there is the possibility of spontaneous appearance of the disease in previously healthy animals.

## Absorption Line Spectrum of the Quasi-stellar Object 3C 191

BAHCALL<sup>1</sup> has pointed out that in the absorption line spectrum for ions in the gaseous envelope of 3C 191, there is a correlation between the ionization potential and  $\Delta z$ , the difference between  $z$  (the red-shift of the absorption line spectrum for any ion) and  $\bar{z}_{em}$  (the mean red-shift of the emission line spectrum). Fig. 1 indicates, as a set of vertical lines, the spread in  $\Delta z$  values derived from curves fitted by Burbidge and Lynds<sup>2</sup> to four sets of measurements<sup>3,4</sup>. In the figure, the ionization potential plotted is that of the atom or ion having one more electron than the absorbing ion; while  $\Delta z$  is defined as  $\bar{z}_{em} - z$ .

In an attempt to explain this correlation we take the following simplified model of a quasi-stellar object: the line spectra are assumed to be produced by electron excitation of gaseous material which has a finite velocity of radial flow in the gravitational field of a large central mass. For flow velocities  $\sim 10^3$  km per sec and electron energies  $\leq 100$  eV, the motion of an atom suffers negligible perturbation in the excitation process, so that its initial velocity defines a Doppler component of red-shift for the line spectra produced. Because the velocity is a function of radius but independent of atomic (or ionic) mass, this component is the same throughout the spectra if the excitation occurs in a region of well defined radius, but different for different ions if their excitation conditions have a radial dependence.

We propose that the electrons are emitted from a small source<sup>5-7</sup> and have a narrow energy spectrum. A correlation between  $\Delta z$  and excitation energy then results if both the electrons and the atoms of the envelope are moving in the gravitational field of the massive object with which the central source of electrons and optical continuum radiation may be associated. Fig. 2 shows the essential features of the model. A central object  $M$  is surrounded by an envelope, a thin hollow shell of radius  $R$  across which the velocity of gaseous flow ( $\beta c$ ) and the kinetic energy of the electrons ( $E$ ,  $=\epsilon mc^2$ ) vary continuously. For observable line spectra to be produced, the shell must be optically

Fig. 1.

Fig. 2.

thin both to photons, in the visible region, and to electrons. Ions resulting from electron excitation may then produce absorption lines from the optical continuum, while emission lines arise from the recombination of these ions in the same envelope.

If it is assumed that the relevant physical parameters vary continuously throughout the envelope, without regard to the exact location of emission and absorption line regions, then a positive sign for  $\Delta z$  may be obtained for either of two possible systems: in one, the envelope is expanding, with decelerating motion, and has the absorption line region inside the emission line region; in the other, the envelope is contracting, with accelerating motion, and has the absorption line region outside the emission line region. Three aspects of the system have to be examined in order that a definite relationship between  $\Delta z$  and excitation energy may be established.

(a) In the particular case illustrated in Fig. 2, the electrons are emitted with less than their escape velocity and attain a maximum excursion radius, at which the gaseous flow velocity is defined as  $\beta_0 c$ , while the material in the shell, which in this case is taken to be expanding, has a velocity exceeding its escape value.

The total energy for an electron in the gravitational field may be written as

$$mc^2(1 + \epsilon) - \frac{mMG}{R} \quad (1)$$

Then the non-relativistic, ( $\beta \ll 1$ ), equation of motion for an atom of the envelope moving with velocity  $\beta c$  at radius  $R$ , when combined with an equation representing the conservation of the quantity (1) with respect to change in  $R$ , gives

$$\epsilon = \frac{1}{2} (\beta^2 - \beta_0^2) \quad (2)$$

(b) We take the excitation energy to be equal to the sum of the kinetic energies of electron and atom in their centre of mass system. Assuming that  $\epsilon \ll 1$ , we obtain for the excitation energy the approximation,

$$mc^2 \left[ \frac{1}{2} \beta^2 + \left(1 + \frac{1}{2} \beta^2\right)(\epsilon \pm \beta \sqrt{2\epsilon}) \right] \quad (3)$$

The double sign in the last term expresses the fact that two-way electron flow in the expanding envelope gives two different excitation energies for each value of  $\beta$ . From (3), and using (2), we may plot curves showing excitation energy as a function of  $\beta$  for any value of  $\beta_0$ . Each curve has a minimum at  $\beta = \beta_0$ .

(c) As we are concerned with observed differences in red-shift, each value of  $\Delta z$  has to be related to a velocity difference. We assume that the emission lines originate in

a region with mean velocity  $\beta_e c$ , and we define  $\Delta\beta$  as  $\beta - \beta_e$ . The corresponding red-shift difference depends not only on  $\Delta\beta$  but also on any recession velocity  $\beta_e c$  which the whole quasi-stellar object may have relative to the observer.

The usual formula for  $z$  as a function of  $\beta$  gives, on relativistic addition of velocities,

$$\Delta z \approx \left( \frac{1 + \beta_r}{1 - \beta_r} \right)^{\frac{1}{2}} \Delta\beta \quad (4)$$

From these considerations we may therefore derive  $\Delta z$  as a function of excitation energy, which is equivalent to the ionization potential, in terms of the parameters  $\beta_r$ ,  $\beta_0$  and  $\beta_e$ .

We make a tentative fitting to the experimental data of Fig. 1 for different values of  $\beta_0$  and  $\beta_e$ , and for two particular values of  $\beta_r$ .

For  $\beta_r = 0$ , representing a system with its centre stationary with respect to the observer, the best fitting curve shown as a dotted line in the figure is calculated for  $\beta_0 = 10.5 \times 10^{-3}$  and  $\beta_e = 6.3 \times 10^{-3}$ . It does not, however, give a  $\Delta z$  variation of the required magnitude for the range of ionization potential plotted.

For  $\beta_r = 0.79$ , corresponding to a recession velocity given by a Doppler interpretation of the mean emission line red-shift<sup>8</sup>  $z_{em} = 1.946$ , the best fitting curve—shown as a solid line in the figure—is calculated for  $\beta_0 = 10.5 \times 10^{-3}$  and  $\beta_e = 9.4 \times 10^{-3}$ ; it clearly shows satisfactory agreement with the experimental data. The parameters  $\beta_0$  and  $\beta_e$  have consistent signs only for the case of an expanding envelope, while the small difference between their values may be attributed to a finite diffusion distance between the points of ion production and recombination.

In our model there are two difficulties which could affect its validity. The first is that the mean free path for interaction of the incident electrons must be at least comparable with the thickness of the shell in which the line spectra originate. Currently accepted figures for interaction cross-sections and envelope densities give a shell thickness  $\leq 10^{10}$  cm. A supply of gaseous material with the required velocity of expansion at a given radius could not be maintained for any length of time by a spherical shell of this thickness, although it could perhaps be maintained by a filament of spiral form, such as a stream of material emitted from a central source which has a small velocity of rotation.

The second difficulty is that there must be some process for the production of electrons with a sufficiently narrow

### Probable Values of the Time of Rise for the Forthcoming Sunspot Cycles

THE values of the time of rise corresponding to the successive sunspot cycles do not seem to show periodicity<sup>1</sup>. If we consider, however, the values of the time of rise for the cycles of the same polarity, that is, the cycles corresponding to the odd and even values of the current number  $N$  separately, we find a more or less clear tendency for the minima of the time of rise to recur every eight cycles for cycles with  $N = 2K + 1$  and every ten cycles for cycles with  $N = 2K$ ,  $K = 0, \pm 1, \pm 2, \dots$

I shall show here that each of these two groups of cycles,  $N = 2K + 1$  and  $N = 2K$ , can be subdivided into two subgroups each of which presents an individual periodic variation. The periods of these variations are very probably multiples of eight sunspot cycles for cycles with  $N = 2K + 1$  and ten sunspot cycles for cycles with  $N = 2K$ . In fact, if we consider the values of the time of rise  $T_R^*$  corresponding to the sunspot cycles  $N = -12$  (1610.8–1619.0) to  $N = 3$  (1775.5–1784.7), determined on the basis of the smoothed mean monthly relative sunspot numbers<sup>2</sup> as well as the values of the time of rise  $T_R$  corresponding to the latter sunspot cycles,  $N = 4$  to  $N = 19$ , determined on the basis of the observed mean monthly relative sunspot numbers<sup>1</sup>, then the existing observational data show that these values can be satisfactorily represented with the help of the following relations

#### (a) ODD CYCLES

$$T = \left[ a_1 - b(3 - \psi_1) \sin(N-1) \frac{2\pi}{64} \right] \cos^2(N-1) \frac{2\pi}{8} + \left[ a_2 - 2b \sin(N-1) \frac{2\pi}{24} + 4b \cos^2(N-1) \frac{2\pi}{24} \sin^2 \frac{N+1}{4} \frac{\pi}{2} + \psi_2 \right] \sin^2(N-1) \frac{2\pi}{8} \quad (1)$$

#### (b) EVEN CYCLES

$$T = \left[ a_3 - b \sin(N-5) \frac{2\pi}{40} + \frac{3}{2} b \sin(N-5) \frac{2\pi}{5} - \psi_3 \right] J + a_4 \left[ 1 - \frac{1}{4} \cos(N-1) \frac{2\pi}{20} \right] (1-J) \quad (2)$$

energy spectrum. The decay of  $\pi$  mesons<sup>9</sup>, if these are of low energy  $\ll 5$  MeV, may provide a suitable source.

We conclude that a correlation of the observed form existing between  $\Delta z$  and ionization potential can provide, in terms of the model described here, an estimate of recession velocity. In the particular case of 3C 191, the present experimental data are consistent with a Doppler interpretation of the mean emission line red-shift.

I thank Professor W. J. G. Beynon for the opportunity of pursuing this research at the University College of Wales. For a number of valuable discussions I am indebted to Dr R. R. Hillier, University of Bristol, Mr J. J. Marek,

where  $J = 1$  for the sunspot cycles with  $N = 10K$ ,  $10K-2$  and  $10K-4$ , and  $J = 0$  for the sunspot cycles with  $N = 10K-6$ ,  $10K-8$ ,  $K = 0, \pm 1, \pm 2, \dots$ .  $a_1 = 6.4$ ,  $a_2 = 5.0$ ,  $a_3 = 4.65$ ,  $a_4 = 4.4$  and  $b = 0.85$ .

In relations (1) and (2) the quantities  $\psi_1$ ,  $\psi_2$ , and  $\psi_3$  represent additional periodic terms acting only during certain sunspot cycles, that is

$$\psi_1 = 2 \left[ 1 - \frac{3}{4} \sin(N-7) \frac{2\pi}{40} \right] \sin^2 \frac{N-1}{4} \frac{\pi}{2}$$

$$\psi_2 = \frac{2}{3} b \cos N \frac{2\pi}{24} \cos K\pi, N = 4K-1, K = 0, 1(6, 7) 12, 13, \dots$$

$$\psi_3 = \frac{3}{2}b \cos N \frac{2\pi}{40} \cos K\pi, N = 2K-2, K = 1, 0 \quad (19, 20)$$

29, 30, ...

The continuous lines (a) and (b) in the upper part of Figs. 1 and 2 represent, respectively, the first and the second term of relations (1) and (2). In the lower part of these figures the small circles represent the observed values of the time of rise while the dots connected with the dashed lines illustrate the values of  $T$  computed with the help of relations (1) and (2).

Table 1 gives the values of  $T$  as well as the observed values of the time of rise  $T_R^*$  (for the sunspot cycles  $N = -12$  to  $N = 3$ ) and the time of rise  $T_R$  (for the sunspot cycles  $N = 4$  to  $N = 19$ ). It can be seen that relations (1) and (2) represent the values of  $T_R^*$  and  $T_R$  with an accuracy

equal to  $(1 - \frac{\sigma}{T_R})$  100 per cent = 97 per cent. Despite this

high degree of accuracy, however, the values of the time of rise for the forthcoming sunspot cycles found by extrapolating equations (1) and (2) should be considered with due caution, because in these relations some periodic terms with periods as long as sixty-four cycles are present, while the observational data on which relations (1) and (2) are based do not refer to more than thirty-two cycles.

I showed earlier<sup>3</sup> that the mean annual values  $[R_m]$  of the relative sunspot numbers during the year of maximum solar activity, as well as the maxima  $R_{max}$  and the minima  $R_{min}$  of the mean monthly relative sunspot numbers during the same year, can be satisfactorily represented as functions of the time of rise  $T_R$  with the help of the relations

$$[R_m] = C + 2 T_0 (T_0 - T_R)^2 + T_0 Y \quad (3)$$

$$R_{max} = a^2 + 2 T_0' (T_0' - T_R')^2 + a Y + 4 T_0' \sin \left( N - \frac{a}{2} \right) \frac{2\pi}{8} \quad (4)$$

$$R_{min} = T_0'^2 + (T_0' + 1) (T_0' - T_R')^2 + \frac{1}{2} T_0' Y \quad (5)$$

where  $T_0 = 5.76$ ,  $T_0' = 6.3$ ,  $a = 9.0$ ,  $C = 2T_0^2$  for the cycles  $N = 7-19$  and  $C = 2T_0(T_0 - 1)$  for the cycles  $N = -3$  to 6, but with cycles  $N = 0$  and  $N = 1$ ,  $C = 2T_0(T_0 + 1)$ . The term  $Y$  is an exponential term of the form

$$Y = \frac{n}{10-n} \exp(n-9)$$

where  $n = 0, 1, 2, \dots, 9$  for each decade of cycles, the value  $n = 0$  corresponding to the sunspot cycles  $N = -10, 0, 10, 20$ , etc.

It is therefore of interest to investigate to what extent the accuracy given by relations (3), (4) and (5) will be influenced if instead of  $T_R$  we use in these relations the new parameter  $T$  defined with the help of equations (1) and (2). The results are shown in Fig. 3, where the small circles connected with continuous lines show the values of  $R_{max}$ ,  $[R_m]$  and  $R_{min}$  respectively given by the observations, while the dots connected with dashed lines give the values of the same quantities computed with the help of relations (3), (4) and (5). The probable values of  $[R_m]$  for the forthcoming cycles  $N = 20, 21, \dots$  are also given in Fig. 3 and it can be seen that the representation of the already available values of these three quantities as functions of  $T$  is very satisfactory.

For the current cycle  $N = 20$  the value of  $T$  computed with the help of relation (2) is equal to  $4.1 \pm 0.1$ . If therefore we take into account that the minimum of cycle  $N = 20$  occurred in 1964.7, we reach the conclusion that the maximum of cycle

1	6.4	6.3	17	3.8	3.7	33	6.4
2	3.5	3.5	18	3.2	3.2	34	5.5
3	2.9	2.9	19	3.3	3.3	35	3.3

$N=20$  will occur probably in  $1968.8 \pm 0.1$ . According to relations (3), (4) and (5) the values of  $[R_m]$ ,  $R_{\max}$  and  $R_{\min}$  for this cycle will be respectively

$$[R_m] = 98.1 \pm 4.0 \quad R_{\max} = 132.3 \pm 8.0 \quad R_{\min} = 75.0 \pm 5.0.$$

It should be noted that King-Hele<sup>4</sup> has recently found that the time of rise for the sunspot cycles  $N=20$  and 21 will be equal to  $T_R=3.4$  and 3.8 years, respectively. On the other hand, for  $T_R=4.1$  years, King-Hele's relation  $(R_m - 16)T_R^2 - 10^{-5} (R_m - 100)^4 \approx 1401$  gives two values for  $R_m$  of which the smallest (99.3) differs little from the value of  $[R_m]$  reported here (98.1) for the sunspot cycle No. 20.

## PLANETARY SCIENCE

### Rotational Speed of the Upper Atmosphere: an Increase with Height above 200 km

THE average speed of rotation of the upper atmosphere can be determined by analysing small changes in the inclinations of satellite orbits to the equator. Previous studies<sup>1,2</sup> have indicated that, on average, the upper atmosphere at heights of 200-300 km is rotating faster than the Earth: the mean value obtained for the ratio  $\Lambda$  of the

Fig. 1. Values of  $\Lambda$  obtained.

rotational speed of the atmosphere to that of the Earth was  $\Lambda = 1.27$ , which corresponds to a mean west-to-east wind speed of 100 m/s in middle latitudes. These previous studies, however, were not accurate enough to allow any definite conclusions to be drawn about the variations of  $\Lambda$  with height, time or latitude.

Recently we completed an analysis of the changes in the orbital inclinations of the following nine satellites: 1962 $\beta$ x, 1962 $\beta$ 1, 2, 5 and 6, 1965-95B, and 1966-51A, B and C. Their inclinations range between 49° and 90°, and the heights to which the values of  $\Lambda$  apply, taken as half a scale height above the mean perigee height, range between 200 and 260 km.

The values of  $\Lambda$  obtained, which are more accurate than before, are plotted against height in Fig. 1, with their estimated standard deviations and an unweighted least-squares line through the points. Fig. 1 justifies the conclusion that the average angular velocity of the upper atmosphere increases from about 1.1 at a height of 210 km to about 1.4 at 260 km. The corresponding mean west-to-east wind speeds in middle latitudes would be 30 m/s at 210 km, increasing to 130 m/s at 260 km. The values obtained previously<sup>1,2</sup>, although less accurate, are also consistent with this conclusion.

For two of the satellites in Fig. 1, 1966-51B and C, for which the average value of  $\Lambda$  over the whole lifetime is 1.0, it has been possible to obtain values of  $\Lambda$  over a much shorter time interval centred in August 1966 when perigee was near the sunset line, with the local time between 18 and 21 h (ref. 3): over this time interval both satellites yield values of  $\Lambda$  near 1.5, which suggests that the west-to-east motion is greatest in the early evening.

### Plasma Resonances of the Magnetosphere

THERE have been many investigations of resonance phenomena in geophysics, for example, the Schumann resonances of the Earth-ionosphere cavity which is excited by lightning flashes. Theoretical attempts have been made to determine possible hydromagnetic resonances of the magnetosphere which should be excited by the solar wind. Under conditions of axial symmetry it is possible to obtain uncoupled solutions for poloidal and toroidal modes. Carovillano and Radoski<sup>1</sup> have recently considered a perfectly conducting plasma, magnetized by a dipole field, in which the plasma density function was expressed in a generalized form, thus allowing their model to incorporate some of the observed features of the magnetosphere. Their calculations for the toroidal modes, and also for the poloidal modes, indicate that the eigenperiods for such a model magnetosphere should lie in the geomagnetic micropulsation range, in agreement with the conclusions reached by a number of other workers.

In practice there are considerable departures from axial symmetry in the magnetosphere and so there arises the question of whether it is possible to observe anything which approximates to axially symmetric resonant modes. The vast amount of rather confusing and often contradictory information in the literature on the characteristics of micropulsations recorded at different localities has so far left this question unanswered.

Using techniques similar to that described by Mainstone and McNicol<sup>2,3</sup>, daily micropulsation spectra in the form of sonagrams covering the Pc3-Pc4 range have been produced

at a number of stations, particularly at Esk near Brisbane, Toolangi near Melbourne, in the eastern part of Australia, and in the United States at Cougar Mountain near Seattle. A careful examination of these sonagrams provides strong evidence in favour of the existence of hydromagnetic resonances associated with (to all intents and purposes) axially symmetric modes; as well as these there are other resonances which are most probably not axially symmetric.

Figs. 1 and 2 are examples of sonagrams of  $Pc3$ – $Pc4$  activity at Esk and Seattle on days of weak geomagnetic agitation. Despite the differences of latitude, longitude, hemisphere and time of year, a recognizable modal pattern can be traced in the frequency range 0–50 mc/s, consisting of two predominant spectral lines and evidence of a third. The two lower frequency modes are usually detectable on sonagrams throughout the entire day while the upper one is more readily seen by day than by night—this behaviour is illustrated in Fig. 3.

The excitation of the various modes is rather variable from day to day, but the frequencies remain relatively constant. When gross changes in frequency do occur they

are usually smooth and may take place over 3 or 4 h as in Fig. 2. As far as can be ascertained, on any one day the frequencies of corresponding modes observed at Esk and Toolangi are identical; however, their relative amplitudes at the two places are not constant. The same resonances have been seen on sonagrams from Townsville in North Queensland, at a relatively low geomagnetic latitude of  $28^\circ$  S. For the purposes of discussion these apparently invariant features of magnetospheric activity will be designated  $X$  modes.

The sonograph spectrum analyser allows spectra to be produced either with coarse frequency resolution ("wide-band" as in the illustrations in this paper), or alternatively with better frequency resolution, and consequent degradation of timing, using the "narrow-band" filter. Sonagrams made by the latter method indicate the existence sometimes of sharp single lines corresponding to the  $X$  resonances, but usually some splitting occurs and this gives rise to a fine structure of closely spaced lines.

The advantages of the sonagram method of dynamic spectrum presentation lie in the optical integration which

Fig. 1. Esk. June 11/12, 1963.  $E_y$  component. Very weak excitation of  $X$  modes during the day.

Fig. 2. Cougar Mountain. January 20, 1964.  $H_x$  component. Excitation of  $X$  modes with slow change in frequency.

Fig. 3. Esk. November 4/5, 1963.  $H_x$  component.

Fig. 4. Toolangi, September 22, 1963.  $H_x$  component. A complex pattern of excitation of  $X$  and  $Y$  modes during a severe magnetic storm.

is inherent with this type of display, making the recognition of invariant features relatively simple. Recent work, however, of a different kind by Fooks and Morgan<sup>4</sup>, who have published several examples of micropulsation power spectra, and by Nwaigwe, Hall and Usher<sup>5</sup>, may reasonably be interpreted as evidence of the detection of  $X$  modes in England. The latter authors give an example of different N.-S./E.-W. behaviour of simultaneous oscillations having frequencies which correspond to the resonances identified here; what might be described as the "E.-W. morning enhancement" which they observe is also a prominent feature on the chart records at Esk.

It should be noted that the  $X$  resonances lie in both the  $Pc3$  and  $Pc4$  domains. On occasions there is some evidence on the sonagrams of a still lower frequency mode, particularly during the day—this is in the  $Pc5$  range but as the equipment concerned has a deliberate cut-off below about 5 mc/s, information on the behaviour of this mode is rather scant. On the other hand the weak excitation of higher order modes is not uncommon.

At times of greater geomagnetic agitation such as in the stormy period after sudden commencement the micropulsation spectrum can become very complex. The activity at Toolangi on such a day, September 22, 1963, is shown in Fig. 4. Type  $X$  modes are present but there are also modes characterized by a slowly falling frequency during the daylight hours. The mode  $AA'$  is centred at about 50 mc/s; the second harmonic about 100 mc/s is visible, and possibly also the third at about 150 mc/s. In addition there is another mode,  $BB'$ , the frequency of which falls more rapidly during the day. These will be designated  $Y$  modes.

The complex pattern of excitation in Fig. 4 does not appear to be arbitrary. Duncan<sup>6</sup> has published two sonagrams for Adelaide covering consecutive highly disturbed days in September 1960. The first day, September 6, 1960, shows an exceedingly detailed agreement with Fig. 4. On the second day, September 7, the geomagnetic agitation was somewhat less and accordingly the activity was chiefly confined to the lowest of the type  $Y$  modes, a behaviour entirely consistent with that deduced from Toolangi sonagrams during September 1963. Duncan's data refer to the vertical component measured by a large ground loop; at Toolangi recordings have been made of only the horizontal N.-S. component.

The lowest of the  $Y$  modes exhibits internal consistency within a given season. There is, however, a noticeable change in characteristics from one season to another. When this mode appears at a slightly lower frequency than in the example shown it becomes difficult to separate from the  $X$  modes. The excitation of both types of resonance in an overlapping pattern probably explains the bulk of the daily spectra.

From records obtained at Esk and Toolangi there is little to suggest that there is any change in the frequencies of corresponding  $Y$  modes with latitude, although the

well-known general diminution of amplitude towards the equator is observed. Sonagrams from Townsville indicate that the dominant patterns of activity in mid-latitudes are not so easily recognizable at low latitudes, at least in the horizontal N.-S. component, and that there may be another, more variable, source of  $Pc3$ - $Pc4$  pulsations near the equator.

The  $Y$  modes cannot be traced reliably through a 24 h period, because at all times of the year there appears to be a cessation of this type of activity by 18-19 h local time. The spectra of the normal night time  $Pi2$  pulsations indicate a connexion with  $X$  modes. Strong night time  $Pc$  activity, however, can sometimes occur in mid-latitudes and, for example, in the interval 21-23 h on September 22, 1963 (Fig. 4), where it is obviously different in appearance from the  $X$  modes, it may be related to the  $Y$  modes. Some of the activity in the very disturbed early morning hours in Fig. 4 may represent  $Y$  mode excitation. Although spectra of  $Y$  modes from stations at other longitudes would be needed to establish the point conclusively, at this stage it seems most unlikely that such modes represent axially symmetric resonances.

There is insufficient evidence to identify any of the modes discussed here as poloidal or toroidal, but further detailed studies of the mode structure of micropulsations may well help to resolve some of the long-standing problems in this field.

I thank the University of Queensland for study leave and colleagues in Brisbane and Cambridge for discussion.

### Radio Anomalies associated with an Ephemeral Satellite still in Orbit

ATTENTION was recently directed in *Nature* to some radio reception anomalies observed in 1962, 1963 and 1965 at several different locations receiving the VLF stations *GBR* (Rugby) on 16.0 Kc/s and *NBA* (Panama Canal Zone) on 18.0 Kc/s. These anomalies consisted of an interfering signal just off the nominal transmitted frequency by some  $10^{-7}$  parts, sometimes above the nominal value and sometimes below it. The interfering signal was often as strong as or stronger than the *GBR* or *NBA* transmissions, depending on the location of the receiving station. Two of the possible explanations for these

anomalies have been discussed—nearby unknown transmitters operating on the same frequencies<sup>1,2</sup>, and an alternate antipodal transmission path<sup>3</sup>. I have studied the *Nature* report and others<sup>2-5</sup> and offer some independent evidence of high frequency radio reception anomalies and a third possible explanation.

Early in January 1961 I listened to the high frequency time signals of *CHU* (Ottawa, Canada) on 7.33 Mc/s at Pacific Palisades, California. Occasionally, for periods of 30 min and more the signal, usually weak at my location, was strong enough not to require an external antenna. To examine this phenomenon further, I monitored *CHU* on 7.33 Mc/s almost continuously each evening during February and March 1962. There were many brief periods when the signal-to-noise ratio became very large, sometimes reaching 18 dB (Table 1, line 1, except last column).

At first, I assumed these enhancements would correspond with the onset of evening twilight at a skip zone, but my early 1962 records clearly demonstrated that this was not the case for more than 80 per cent of the enhancements. *CHU* was monitored again in early 1963 between January 20 and March 3. Once more I found a definite pattern of reception enhancements, but it differed from that of early 1962 (Table 1, line 2). I tried unsuccessfully to correlate the times of enhancements with overhead passages of *ECHO* I and other artificial satellites.

During November and December 1965 I made reception measurements of *CHU* on 7.33 Mc/s and again found periodic enhancements. More than 90 per cent of them had a very definite pattern which differed from the previous patterns (Table 1, line 3). Additional data for *CHU* were taken during December 1966 and January 1967 by B. A. Bagby and myself at Pacific Palisades. Again there was a very definite pattern to most of the enhancements, which differed from all preceding ones (Table 1, line 4). It was obvious that the time between enhancement periods was different at each succeeding epoch, and that the daily advance was also changing. If these enhancements were due to reflexions from the passage of a particular Earth satellite through the upper atmosphere, then that satellite had a changing orbital period. I tried to correlate the various reception enhancements with the osculating orbit of the natural Earth satellite previously discussed in *Nature*<sup>6</sup>, but because I was unable to account for all the various radio enhancement periods as being due to the natural satellite, I put the task aside temporarily.

I have re-evaluated the *CHU* radio data, and have found that the source of the earlier difficulty was the very elliptical orbit of the natural object. I had assumed that the apparent period deduced from the radio anomalies would always be the simple reciprocal addition of the object's sidereal period and that of the Earth's rotation, which is true only for a circular orbit. Allowing for the orbital situation at each radio epoch, I related the *CHU* radio enhancement records on 7.33 Mc/s in Table 1 to the osculating orbit of the natural satellite on each occasion (Table 1, last column).

I recently attempted to find a correlation between the *GBR* and *NBA* radio reception anomalies and those found

for *CHU*, and tentatively concluded that the VLF radio anomalies could also be caused by the natural satellite. This would be confined to radio reflexions taking place near the object's perigee. Here the charged cloud associated with the passage of the body through the upper atmosphere would be large enough<sup>7</sup> to reflect 16 and 18 Kc/s signals. This would temporarily provide an alternate transmission path similar to, but shorter than, that suggested by Isted<sup>3</sup> as the cause of the VLF interferences. I computed the geocentric latitude and longitude of the perigee of this satellite on the various occasions of VLF anomalies and found that exceptionally favourable conditions were present during both the May-June 1962 and November-December 1965 periods. Fair conditions were present during the April 1963 period. For June 11, 1962, the perigee dip occurred near 14° S., 167° W. at 0300 U.T. For November 13, 1965, the perigee dip was near 30° N., 149° E. at 0800 U.T. These positions are approximate to the estimated locations of the postulated second transmitter<sup>1,2</sup> in each case. The frequency shifts observed ( $\approx 10^{-7}$  parts) on 16 and 18 Kc/s for the secondary VLF signals<sup>1,2</sup> could have been due to the satellite's approaching or recessional velocity relative to both the receiving and transmitting stations. The rarely occurring maximum possible displacement, due to this Doppler effect, would be  $\Delta f/f = 5.4 \times 10^{-5}$ . More often this value would be much lower, and would have varied slightly during the brief enhancement period, as was observed<sup>1</sup>.

Allowing for differences in the orbital situation, the *GBR* records of November 1965 (ref. 1) are almost replicas of the *CHU* records for that same period, with reference to time of day and periodicity. The 1962 and 1963 VLF data and the 1961 HF data are too meagre for such a positive comparison.

In order to compare the radio anomalies with the orbit of the natural satellite beyond the period of time covered in my earlier paper<sup>6</sup>, I made more optical observations. With the aid of the indirect *CHU* radio evidence, this was accomplished photographically near the object's apogee on both January 18 and 20, 1967. Further optical observations are given in Table 2. Because the *CHU* radio experiment was also being run during January 1967 the two sets of data could be directly compared. The successful pairs of plates (out of sixty pairs taken) were each exposed shortly after a radio enhancement period had begun at Pacific Palisades.

With the recent optical observations, orbital elements have been derived to cover the time period since October 25, 1965 (Table 3). The solution was quite unique, converging very rapidly during the trial and error computational process. The slowly changing inclination is not without precedent. This effect, due to the upper atmosphere near perigee, has been discussed at length by Nigam<sup>8</sup> and others<sup>9</sup>. After the orbit solution was com-

Table 2

Date	Time (U.T.)	Right ascension	Declination	Magnitude
Jan. 18, 1967	05.18.35	5h 00m	+46.0°	8

### Mid-Ocean Ridge in the Mouth of the Gulf of Aden

For the past thirty years it has been assumed that the seismically active structure of the Carlsberg Ridge is connected with the seismically active East African Rift System through the Gulf of Aden. Details of this connexion have emerged during the International Indian

Ocean Expedition<sup>1-3</sup>, but sounding and magnetic profiles in the entrance to the Gulf of Aden have been too sparse to determine the line of the median structure. The track that R.R.S. Discovery followed during Cruise 16 in March 1967 (Fig. 1) was designed to criss-cross the epicentre belt and fill in this gap. Bathymetric and magnetic data obtained confirmed the existence of a mid-ocean ridge structure in the Gulf of Aden west of the Owen Fracture Zone; we suggest the name "Sheba ridge" be given to this feature.

Profiles obtained along the sections B-X of the track are presented in Fig. 2. Depths are plotted in corrected fathoms and the magnetic anomalies are shown after deduction of the regional gradient taken from ref. 4 but without correction for daily variation. The soundings have been combined with other soundings in the area and used to revise the relevant portions of contour charts based on British Admiralty 1 : 1,000,000 plotting sheet areas 158 and 159 (A. S. Laughton, personal communication). The significant features of these charts are summarized in Fig. 1.

The median valley has been traced as a continuous structure (with one displacement) from the Alula-Fartak trench to the Wheatley Deep, a trough on the Owen Fracture Zone 600 fathoms below the Indus abyssal plain<sup>3</sup>. Its trend changes continuously from E.-W. at 55° E. to N.W.-S.E. at the Owen Fracture Zone. The

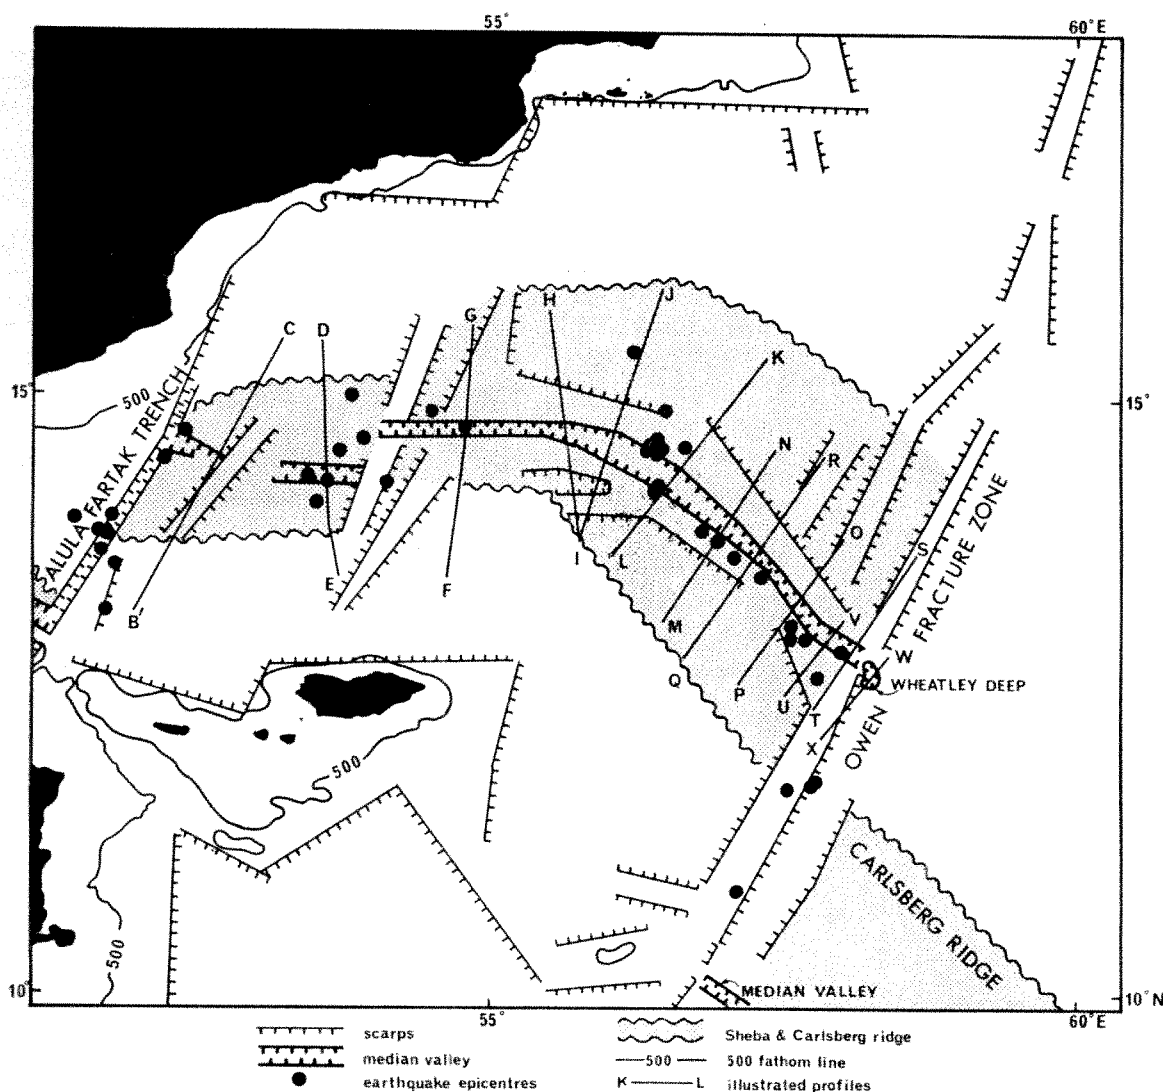

Fig. 1. Structural features of the Gulf of Aden and epicenters from Alula-Fartak trench to Owen Fracture Zone, and positions of profiles illustrated in Fig. 2.

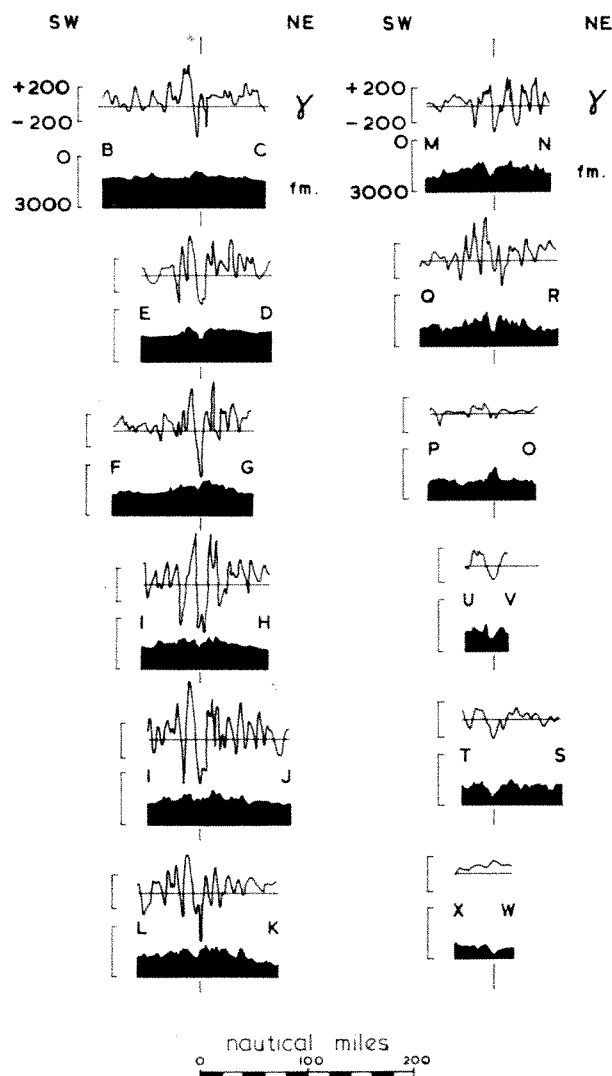

Fig. 2. Bathymetric and magnetic profiles B-X inclusive.

median valley is clearly recognizable on all the profiles except profiles BC and PO; Fig. 1 shows how it corresponds with the epicentre belt. In the six western profiles, as far as LK, the valley is clearly identified by a large negative median magnetic anomaly. On profiles MN and QR there is no unique large anomaly while on profile PO there is no large anomaly at all. The median anomaly reappears with smaller amplitudes on the short sections UV and TS. These profiles are in the Owen Fracture Zone: Matthews, Vine and Cann<sup>6</sup> have suggested that the pattern of magnetic anomalies is expunged in a fault zone by extensive brecciation and hydrothermal alteration of the permanently magnetized rocks.

The track WX lay just to seaward of the Owen Fracture Zone and crossed the south-eastern edge of the Wheatley Deep which has a maximum depth of 3,100 fm.; no significant magnetic anomalies appear along the part of this track opposite the faulted end of the median structure. Steaming south from X, the ship passed over the foothills of the Carlsberg Ridge just east of the Owen Fracture Zone and over the median anomaly at 10° N., 57° E. at a point which lies precisely on the line of the median structure at the northern end of the Carlsberg Ridge<sup>3</sup>. This result confirms the measured displacement of the axis of the ridge as 170 nautical miles right lateral.

The median line of the ridge is displaced 100 miles to the left at the Alula-Fartak trench (Fig. 1), and Sykes<sup>6</sup> has identified this feature as a transform fault<sup>7</sup>. Examina-

tion of the contoured charts of magnetic anomalies and of topography (unpublished) makes it clear that another transform fault lies on a line between the kink in the edge of the continental shelf just west of Socotra and a corresponding kink in the Arabian coastline near 17° N., 55° E. The displacement of the axis of the ridge is 30 miles left lateral at this fracture, which is marked by earthquake epicentres.

The redrawn topographic contour chart shows a strong lineation of ridges and troughs running parallel to the median valley in the western part of the area. Near 13.5° N., 57.5° E. (on profile QR) this trend is crossed by a system of larger and smoother features running perpendicular to the first, parallel with the Owen Fracture Zone. The evidence indicates that the median valley transects these Owen Fracture Zone ridges and terminates in the Wheatley Deep.

The contoured chart also shows that the median valley breaks through the block faulted ridge immediately east of the Alula-Fartak trench at 14.5° N., 52.5° E. and enters the trench itself near its northerly end. If one makes the very reasonable assumption that the system of ridges parallel to the Owen Fracture Zone and to the Alula-Fartak trench are horst and graben features associated with the faulting in these shear zones, then it is clear that the latest phase of opening along the median line of the mid-ocean ridge postdates the formation of the fracture zones, and that the horst and graben features postdate the formation of the principal part of the central rough zone in the Gulf of Aden. These horst and graben blocks which run N.E.-S.W. parallel to the fracture zones form the dominant topographic lineation in the part of the Gulf of Aden west of the Alula-Fartak trench. It can also be argued that the formation of the Wheatley Deep must be post-Pleistocene because it has not been filled by the sediments of the Indus Cone. These sediments must have been deposited during the Pleistocene because the absence of turbidity currents (deduced from the absence of broken cables, Heezen—personal communication) across the cone suggests that they are not being deposited at present. If that is so the following sequence of events has occurred in the Gulf of Aden. Formation of the Sheba Ridge structure parallel to the median line; formation of the horst and graben N.E.-S.W. structures (Pleistocene or earlier) and formation of the median valley (post-Pleistocene).

## PHYSICS

### Effect of Pressure on the Viscosity of Water

ACCURATE values for the viscosity of water at various temperatures and pressures are necessary both to the chemist, who may require to relate viscosity with other phenomena, such as electrical conduction in aqueous solutions, and to the engineer, who may require the information in the solution of heat transfer and flow problems. It has been observed that above about 33° C

the viscosity of water increases with pressure, and that below this temperature, initially the pressure effect is negative but at about 1,000 kg/cm<sup>2</sup> the viscosity relative to 1 atm. exhibits a minimum. Presumably at this pressure the structured regions occurring in water have been partially destroyed and the behaviour is more like that of a "normal" liquid.

Horne and Johnson<sup>1</sup> have recently published results obtained with a rolling-ball viscometer in the range 1–2,000 kg/cm<sup>2</sup> and in the temperature range 2° to 20° C. The results disagree with the low temperature measurements of Bett and Cappi<sup>2</sup>. While Cappi's results suggest that the rate at which the negative coefficient changes between 20° C and 2° C is fairly uniform, Horne and Johnson's results indicate a gradual change until 4° C is reached, and below this temperature the pressure coefficient is shown to increase abruptly. This is apparent in Fig. 1 where it can be seen that Cappi's 10° C isotherm has a steeper slope than the 4° C and 6.2° C isotherms of Horne and Johnson, while Cappi's 20° C isotherm corresponds to the 10° results given by Horne and Johnson.

The temperature of 4° C is significant for water because at this point the effect of thermal expansion becomes greater than the contraction due to the thermal destruction of ordered regions of molecules. This gives rise to the well known minimum in the specific volumes at this temperature. Horne and Johnson's results indicate that at 4° C there is a sudden increase in the effect of pressure on viscosity while Cappi's observations show no sign of this.

I have made preliminary measurements using a rotating cylinder viscometer, which has been previously described<sup>3</sup>, at pressures up to 230 kg/cm<sup>2</sup> and at temperatures between 12.5° C and 108° C. At low temperatures it can be seen that these results are in agreement with those of Bett and Cappi rather than with those of Horne and Johnson. At higher temperatures measurements are in agreement with other workers, including those of Moszynski<sup>4</sup>.

Discrepancies such as these present problems in the setting up of formulae representing the properties of water. The anomalous behaviour of water at low temperatures is not correctly indicated by published tables of values, examples of these being the Skeleton Tables of the International Steam Conference<sup>5</sup> and the more recent correlation of Bruges, Latto and Ray<sup>6</sup>. There appears to be a need for more measurements at low temperatures and up to 1,000 kg/cm<sup>2</sup> to remove any doubts which may still exist.

### Wettability and Adhesion of Polyethylene

THE linear relationship found experimentally by Barbarisi<sup>1</sup> between bond strength and  $(1 + \cos \theta)$ , where  $\theta$  is the contact angle for epoxy-polyamide adhesive on polyethylene, is of technological importance and merits more careful analysis.

The relationship was arrived at on the basis of the well-known equation between the reversible work,  $W$ , required to separate liquid from 1 cm<sup>2</sup> of a solid surface, leaving adsorbed film on the surface in equilibrium with the liquid, and the contact angle

$$W = \gamma_{LV}(1 + \cos \theta) \quad (1)$$

where  $\gamma_{LV}$  is the surface tension of the liquid. This equation indicates that for a given liquid, the greater the degree of wetting of a surface, the stronger is the bond; a chosen solid which is completely wetted by the liquid will give  $W = 2\gamma_{LV}$  (experimentally found bond strengths are invariably much less than theoretical values)<sup>2</sup>.

Low energy solids, for example, polymers, can be characterized by their critical surface tension  $\gamma_c$ , a quantity which was found empirically by Zisman and co-workers<sup>3</sup>. The precise significance of  $\gamma_c$  is still uncertain, but Fowkes<sup>4</sup> has shown that it is almost equal to  $\gamma_s^d$ —the dispersion force contribution to the surface tension of the solid. For polyethylene  $\gamma_c = 31$  dyne/cm and  $\gamma_s^d = 35$  dyne/cm. Because the surface tension of polyethylene will come from dispersion forces, it is justifiable in this case to write

$$\gamma_s = \gamma_s^d \approx \gamma_c \quad (2)$$

Only in the absence of better information is it reasonable to approximate  $\gamma_c$  for  $\gamma_s$  when dispersion forces are known to dominate.

Barbarisi<sup>1</sup> makes the statement that contamination on the surface (of polyethylene) will in general lower the value of  $\gamma_c$ , that is, reduce the ability of a liquid to wet the solid, and therefore recommends pretreatment of the surface. The following arguments demonstrate that

## BRITISH ASSOCIATION SUPPLEMENT—LEEDS, 1967

## "THE ADVANCEMENT OF SCIENCE"

CONVENTION has often required, in recent years, that people should shake their heads with regret and a little scorn at the supposed incomprehensibility of modern science. "Science is fragmented", the saying goes. One way and another there is a widespread belief that the condition of science was much healthier a century or so ago, when it was often possible for intelligent country gentlemen, occupied for most of their time with doctoring or industry, to keep up with what the natural philosophers were writing and often to take issue with them as well. And it is true, of course, that circumstances were very different then. There was less science. The pace of advance was comparatively leisurely, so that there was time for new concepts to be assimilated by people not actively working in a field before they were in turn discarded by the professionals. But even in those supposedly halcyon days, understanding was not always easy to come by. Darwin was in everybody's mind, but appreciation of the more abstract work on which Faraday was engaged was inevitably much more restricted, for example. Since then, there has been no real qualitative change in the character of scientific advance, but merely such a dramatic acceleration of the pace of discovery that things appear to be quite different from what they were.

In circumstances like these it makes no sense to complain about specialization as such. For centuries, and for long before the beginning of modern science, scholars have found that the interesting problems are only solved when effort is concentrated on them. Mediaeval scholars in particular were often firmly wedded to specific tasks—the translation of the Bible from one language to another. For all the ease with which Victorian gentlemen could participate in science, specialists were plentiful in the nineteenth century. A good many of them were as single-minded as any now alive. Just as at present, they would often fail to communicate exciting news to specialists in other fields. In other words, it seems that when it comes to making progress, specialization is not merely a necessity but often a virtue without which scholarship would be diminished. It follows that the only complaint against the specialists which can, in some circumstances, be sustained is that they take too little trouble to acknowledge that the essence of what they do can be enormously interesting and important to other kinds of people. It is not too fanciful to think that the advance of science as a whole consists of the integration into a whole of the separate discoveries of scientists working in fields which seem, at first sight, quite unrelated.

The annual meeting of the British Association, at Leeds this year, is a good time for remembering this, for the association has its roots in the days when it was possible—but, even then, not common—for amateurs to make contributions to the advance of science ranking in importance with the contributions of those who laboured full-time at some laboratory bench. The

records of the old meetings show how easily scientific issues could become matters for public debate between men (but few women) with widely different issues. Over the years, the association has quite properly changed its character with the acceleration of discovery, but it remains, as it should, a means by which a public wider than that of the full-time professionals can be kept abreast of new developments. In doing so it has come up directly against the difficulty of distilling from the continuing torrent of professional activity those developments which may in some sense be called essential. This problem is, of course, one that the association shares with a great many other organizations—responsible newspapers, for example, and the growing number of magazines designed to bridge the gap between the full-time profession as such and the great company of those outside.

The problem is that of reading the fine print and picking out the points at which matters of general interest escape almost without assistance from the technicalities with which they are inevitably accompanied. There is probably a case for saying that the professionals do too little to help outsiders and each other by drawing attention to matters of great importance. Yet there is much that can easily be done, as it is hoped the following pages will show. They are intended to pick out for the interest of a wider readership than that usually concerned with individual articles in this journal problems which seem to have become of special interest and excitement in the past year or so. The selection, it will be seen, is biased. It is mostly concerned with issues which have been raised in this journal, but it does not do justice to all the matters which are at present of great importance—the physiology and chemistry of vision, the mechanism by which platelets clump together in blood and a great many other topics.

## COSMOLOGY

# Radiation from the Origin of Time

THE discovery which has done the most to electrify research in the past year is probably the recognition that the Universe is filled with microwave radiation which is probably in one sense or another a relic of the beginning of time. At present, this bath of radiation seems to be that appropriate to a black-body with a temperature of  $3^\circ\text{K}$ . The supposition is that it is what is left of the exceedingly energetic radiation—gamma rays and the like—that would have been generated if the universe were once compacted into a relatively tiny volume. After roughly  $10^{10}$  years in an expanding universe, the gamma rays have been degraded into microwaves. If this interpretation is correct, the microwave radiation constitutes evidence that the Universe has aged with time, and thus cuts the ground from beneath the theory of continuous creation, one of the objectives of which is to permit a universe whose intensive properties do not change with time. It does not follow, however, that the microwave radiation is final support for the big bang picture of a universe with a beginning in some cataclysmic phenomenon. A pulsating universe in which light elements were refashioned out of heavy elements at each compressed extreme of the cycle would be equally consistent with the existence of the microwave radiation.

The search for the microwave background, and its detection in the past two or three years, owes much to R. H. Dicke and his colleagues<sup>1</sup> at Princeton University. The essence of their position is that the origin of the Universe must have been a state of affairs very much like thermal equilibrium but corresponding to such a high temperature that all elements except hydrogen (and possibly deuterium and even helium) would have evaporated. This implies a temperature of some  $10^{10}$  degrees K, and therefore a black-body radiation with a peak consisting of X-rays somewhat more energetic than those from the annihilation of positrons and electrons. The rate at which this radiation will degrade in wavelength must depend on the rate at which the material universe is expanding. As luck will have it, the atmosphere of the Earth is comparatively transparent to microwaves between one and 20 centimetres, and Dicke's first calculations suggested that the degraded radiation from the primeval universe would fall in this range, which meant that there could easily be profit in a search for this radiation.

In the event, the first direct observations of the contemporary background radiation appeared in the background noise detected by the horn antenna built by the Bell Telephone Laboratories to collect signals from Echo satellites<sup>2</sup>. But the group at Princeton used a more specific piece of apparatus designed earlier by Dicke to pick out spectrally broad sources of radiation in the presence of noise from radio receivers, and which has the further advantage of making a

direct comparison between the microwave background and an artificial source of thermal radiation kept at only a few degrees above  $0^\circ\text{K}$ . The result<sup>3</sup> was a direct confirmation of the horn antenna at the Bell Telephone Laboratories though at a different wavelength, and also some evidence to suggest that the microwave background is isotropic, which is of course essential if the radiation is somehow characteristic of a symmetrically expanding universe. Since then, other points have been obtained on what seems to be a straightforward Planck curve describing the intensity distribution of radiation of different wavelength from a black-body with a temperature of about  $3.3^\circ\text{K}$ , or to a wavelength of roughly two millimetres. The most intriguing method<sup>4</sup> depends on the fact that molecular cyanogen has an electronic excitation with an energy corresponding to a wavelength of 2.6 millimetres, which means that some proportion of the interstellar cyanogen will exist in the excited state, and that the proportion of such molecules—which can be estimated from the strength of the absorption lines due to the two forms of cyanogen in stellar spectra—is a measure of the temperature of the microwave background. Unless there is some quite unexpected error of interpretation, it looks as if the existence of an all-pervading bath of microwave radiation has been proved up to the hilt.

The solid curve in the accompanying diagram (from Howell, T. F., and Shakeshaft, J. R., *Nature*, **210**, 1318; 1966) shows the spectrum of the microwave background in the light of four separate measurements available a year ago. The solid line itself is the theoretical brightness expected from a black-body at a tempera-

ture of  $3^\circ$  K. Brightness is measured in units of ergs  $\text{sec}^{-1} \text{cm}^{-2} (\text{c/s})^{-1} \text{ster}^{-1}$ . The experimental measurement at the peak of the curve is that representing measurements of absorption of light from the stars by cyanogen molecules. The lowest experimental measurement on the solid curve was made at the Mullard Radio Astronomy Observatory, and the other points in the United States at Princeton and the Bell Telephone Laboratories. To the left of the solid line are a number of points representing background microwave radiation from the galaxy which must be expected to swamp the cosmological microwave background at frequencies lower than about 1,000 mc/s. One study of this kind has already been described<sup>5</sup>. There seems at least to be a possibility, much in need of confirmation before it can be considered as anything like a fact, that the effective temperature of the microwave radio background is greater in two directions in the Universe, one above and one below the galactic equator, and there is just a possibility that these apparently preferred directions may somehow be linked with places in the sky at which certain exceptional quasars are located (see page 1059).

What does all this mean? The most immediate value of these new developments is that they provide a further means of access to cosmological questions. One possibility, for example, is that the mere existence of the microwave background will set a limit to the energy with which protons in the cosmic radiation can reach the Earth. Too much energy will imply too great a chance of interacting with some photon from the microwave background. Fortunately the discovery that energetic cosmic ray showers in the atmosphere produced by the arrival of single energetic particles from outside are accompanied by the emission of pulses of radio waves may provide a means of testing whether the limit of energy lies at  $10^{21}$  electron volts,  $10^{22}$  electron volts or at some other level. Another possibility, being followed energetically at Princeton and elsewhere, is that it may be possible to measure directly the motion of the Earth through the microwave background by a sufficiently sensitive measurement of the apparent intensity of the radiation from various directions fixed in space. Although to a first approximation the radiation is isotropic, the velocity of the Earth within the Solar System should be enough to produce a detectable imbalance, leading to a greater flux of radiation from the direction towards which the Solar System is moving, even if this galaxy as a whole is at rest with respect to the microwave background. But what if this galaxy is itself moving relative to the background? Studies like these, in other words, could provide direct evidence about the way in which the galaxy was formed.

Whether the existence of the microwave radiation will quickly help to resolve the differences between competing cosmologies is another matter. But on the face of things, the microwave background does seem to be a piece of evidence that the Universe has changed in the course of time, which seems to argue against steady state theories in which the local character of the Universe remains unchanged from one millennium to the next. It is, however, worth remembering that there may conceivably be other explanations of the microwave background than the degradation of the radiation in an initial big bang—and that the supporters of steady state theories are resourceful people. But

even if the Universe is at present ageing, it does not follow that the origin was a big bang. It could also have been the extreme phase of a huge oscillation. As yet it is not clear how far the microwave radiation will help to distinguish possibilities such as these.

## RADIO-ASTRONOMY

### Smaller Quasars

THE radio sources which are quasars are distinguished from other radio sources in the sky by their small angular diameter. The precise measurement of an extremely small radio source requires a radiotelescope of great size operating as an interferometer, and techniques for doing this have been worked out over the past several years at the Nuffield Radio-astronomy Laboratories at Jodrell Bank by a group of people under Dr H. P. Palmer<sup>1</sup>. Over a period of several years the components of a pair of radiotelescopes have been moved further and further apart until the distance separating them was as great as half a million wavelengths of radiation at 21 cm. The technique consists of comparing the signals from two separate radiotelescopes so as to extract information not merely about intensity but phase as well. Where the distances are so great, it is necessary to use radio links for comparing the signals. By this means radio sources smaller than a quarter of a second of arc have been measured. But is there any possibility of making interferometers with a still greater base length? One difficulty is that even the best microwavelengths and landlines tend to lose quality after some hundreds of kilometres.

It now appears that a way round the problem does exist. A group of radio-astronomers from Canada<sup>2</sup> have been able successfully to use magnetic tape recorders capable of recording accurately a wide band of radio frequencies in such a way as to produce records from two independent radiotelescopes which can later be accurately compared with each other. The standard of time is provided by independent local oscillators controlled by rubidium frequency standards. In one series of observations, two radiotelescopes were separated by 3,000 kilometres or the equivalent of more than 4.5 million wavelengths at a frequency of 448 megacycles per second. With this arrangement, it has been demonstrated that the diameter of at least one quasar (3C 273B) is less than 0.02 seconds of arc.

Plainly this is an important development of technique which is certain to lead to still more refined measurements of the diameters of quasars.

## ASTRONOMY

# Why is the Sun Flat?

OBSERVATIONAL tests of Einstein's general theory of relativity are exceedingly few and far between, and since the twenties observations of the rotation of the orbit of the planet Mercury have provided the most direct support for the theory as a whole. This is why great interest attached to an announcement earlier this year by R. H. Dicke and his colleagues<sup>1</sup> at Princeton of some measurements of the flatness of the Sun, and to their suggestion that this by itself could account for a part of the rotation of the orbit of the planet which has so far been attributed to Einstein's theory. If this assertion is true, it is plain that support for the general theory of relativity will be undermined. In the event, however, admiration for the ingenuity and the accuracy of the measurements of the flatness of the Sun has not been accompanied by a general acceptance of Dicke's reasons for believing the Sun should be flattened. It remains to be decided whether the new evidence goes against Einstein's theory.

The facts are these. The orbit of Mercury rotates slowly with respect to the fixed stars chiefly because of the influence of the other planets, but when these effects have been allowed for there remains a rotation of 43.11 seconds of arc a century to be accounted for. When this was first appreciated at the beginning of the century, a search was made for other explanations than the disturbing influence of the other planets. One possibility then considered was that the Sun might be flattened in such a way as to affect the position of the orbit, although people found it hard to believe that this could happen without more obvious disturbances of the orbit of Mercury than the rotation of the perihelion. In any case, precise measurements of the shape of the Sun were not then practicable. In the event, it may have seemed almost too good to be true that the strictly relativistic calculations of Einstein's theory should imply that there should be a rotation of the orbit of Mercury amounting to 43 seconds of arc a century.

Dicke<sup>2</sup> was the first to suggest, as early as 1964, that this agreement between experiment and observation might not be as comforting as people had supposed. He pointed out that a flattening of the Sun might well account for a good part of the rotation of the perihelion of Mercury. Dicke and his colleagues have now built and operated an exceedingly clever instrument by means of which light from the outer rim of the Sun is scanned electronically around the circumference in such a way that disturbances due to the Earth's atmosphere can be eliminated. The result, which appears to be beyond dispute, is that the radius of the Sun is greater towards the equator than towards the poles by 34 kilometres, or by roughly five parts in a hundred thousand.

What does this imply for the rotation of the orbit of Mercury? Everything depends on the success with which the gravitational forces of the Sun can be inferred from the shape which is observed. If, of course, the Sun were a mass of fluid held together by its own

gravitation, but otherwise at rest, it would be a perfect sphere and it would be possible to infer that the gravitational potential is the same at every point on the surface. (What seems to be the surface would not be a sharp discontinuity between different phases as at the interface between the Earth and its atmosphere, but it would instead be a surface on which the density of solar matter is constant.) The rotation of the Sun as a whole complicates the position, and Dicke says that this accounts for 7 km of the observed flattening, leaving 27 km to be accounted for in other ways. For him, this implies that the external gravitation forces of the Sun are not those corresponding to a perfectly spherical distribution of matter but, rather, to one which is significantly asymmetrical. And if this is indeed the case, some of the observed rotation of the orbit of Mercury—3.4 seconds of arc a century—is to be attributed to flattening of the Sun and not to Einstein's theory of relativity.

This is not a big discrepancy. Even if it is safe to assume that the shape of the Sun is a guide to its gravitational influence on the planets, observation and the predictions of theory would differ by only 8 per cent. This, however, is more than the cosmologists could comfortably ignore, and in any case there remains the puzzle of how to account for flattening of the surface. Dicke suggests that it is enough to suppose that the interior of the Sun is rotating a little more quickly than the surface (which makes one revolution in 25.4 days). One immediate difficulty is that any hypothesis like that must somehow be linked with theories of the rotation of the Sun—and in particular with the awkward question of how since the beginning of the Solar System the Sun can have lost enough angular momentum to explain the comparatively slow rotation now observed.

In the circumstances it is not surprising that Dicke's argument is being studied with the greatest care. Professor I. W. Roxburgh<sup>3</sup> has raised a number of objections, and has, for example, pointed out that if the inside of the Sun were rotating more quickly than the surface, the temperature on the Sun would probably differ by 10 degrees between the equator and the poles. For Roxburgh, temperature gradients within the Sun could account more satisfactorily for the flattening which Dicke has measured and, on that interpretation, observed flattening should have no effect on the gravitational influence of the Sun. Dicke<sup>4</sup> has refuted some of these arguments, but it would be a great surprise if this important question were now forgotten. In the long run, the controversy could do more to improve understanding of the rotation of the Sun and the structure of its interior than to upset the foundations, such as they are, for the general theory of relativity.

## ASTRONOMY

## Continuing Problems about Quasars

THIS has been a frustrating year for those who look for explanations of what quasars are or, even more modestly, for some simple information about the location of these puzzling objects. The outstanding problems remain much as they were described six months ago by Professor F. G. Smith<sup>1</sup>. It is, however, extremely odd that each fresh attempt to test some hypothesis about quasars tends to be inconclusive or even to produce some kind of contradiction.

The first quasars were recognized by the intensity of their radio emission and by their unusual compactness—a few seconds of arc or less. Radio sources like these are often associated with optical sources, and spectral lines tend to be shifted enormously towards the red. Known quasars are now numbered in hundreds. Some of them have optical but not radio emission. Others may be invisible radio sources. The oddness of the quasars is well shown up by the way in which, in the same optical spectrum, absorption and emission lines may be shifted towards the red to different degrees.

The interpretation of the red-shift seems still to be uncertain. If quasars were like ordinary nebulae outside this galaxy, the existence of a red-shift would imply recession and its degree would be a measure of the velocity of recession. In that case, quasars would be extremely energetic sources of radiation at exceedingly great distances. But may the red-shifts be accounted for in some other way, possibly by recognizing that in theories of gravitation, extremely massive bodies would redden light escaping from them? On that interpretation of the red-shift, quasars would be less energetic and less massive but some means would have to be devised for explaining why light from them is shifted to the red—and why so many of them put such a large proportion of their energy output into radio waves. The fact that the output of radiation, light as well as radio, can vary significantly within a few days is something else to be accounted for.

From the beginning there have been hopes that some understanding of the quasar problem would be provided if there were some relationship between the brightness of the quasars and their red-shifts. If, for example, red-shift is a measure of distance, then the faintest quasars should be those with the greatest red-shifts. When there was only a handful of quasars to include in a statistical analysis, the absence of a convincing correlation was not surprising. Now, however, that there are many more objects with which to work, such conclusions as have been drawn are not cheerfully in agreement with each other. Thus one group has claimed that radio observations, at an unusually high frequency, show signs that brightness decreases with increasing red-shift<sup>2</sup>. (The diagram on the next page shows the relationship between red-shift and brightness at 5,000 Mc/s.) Another group, working principally with optical observations, has pointed out that a relationship between red-shift and brightness need not necessarily imply that the quasars

with the greatest red-shifts are also the most distant<sup>3</sup>. How this will be resolved is not at this stage clear, but obviously it would be a great advantage if there were some way of deciding unambiguously how the red-shift of quasars is to be interpreted.

There has also been a search for evidence to suggest that quasars may be distributed in patches in the sky, but this, too, has been inconclusive. On the whole, there is as yet no compelling reason for thinking that the quasars now known are distributed irregularly. At least two attempts have been made to account for what appear to be patches of the sky in which quasars are unexpectedly abundant<sup>4,5</sup>, but it has also been argued that the statistics are not yet good enough to endow the appearance of patchiness with undeniable authenticity.

It remains, however, puzzling that quasars with very large red-shifts (in which the wavelength in Angstroms of the emitted light is multiplied by a factor of three or thereabouts) seem to stand out from the others partly by what seems to be a clustering at one end of the range of red-shifts and partly because they seem to be associated with two patches in the sky above and below the plane of this galaxy. If it should turn out, when there are more quasars with which to make a statistically convincing analysis, that there is indeed some variation of the distribution of quasars with direction in the sky, people will be forced to the conclusion either that quasars are not placed towards the outer regions of the universe or that the universe has some entirely unexpected property—either an anisotropy<sup>4</sup> or an inhomogeneity<sup>5</sup>.

But how to test for some departure of the universe from complete uniformity? The cosmological microwave background has been suggested as one means of doing this, and Wilkinson and Partridge<sup>6</sup> have now made a search for differences in the apparent temperature of this radiation in different directions in the sky. As it happens, they have found that the apparent temperature of the radiation appears to be  $0.016^\circ\text{K}$  higher than the average in a direction roughly corresponding to that in which the quasars with the biggest red-shifts seem to be concentrated. The accompanying diagram shows the results obtained by combining the

results of 80 sweeps, each lasting 24 hours, along a circle in the sky at a declination of  $-8^\circ$ . Wilkinson and Partridge warn their readers of the need not to take this coincidence for proven. It could easily turn out to be a statistical fluke. But evidently there is plenty of scope, and incentive, for detailed statistical analyses of where quasars are to be found.

The question of what quasars are remains remarkably open. It seems, however, to be agreed that individual quasars cannot be single massive stars producing their red-shifts gravitationally. For that to be possible, the stars would have to be so massive and so dense that it is hard to see how large amounts of radiation could ever escape from them. Hoyle and Fowler<sup>7</sup> have suggested one way out of this difficulty by means of a model in which the quasar radiation is assumed to come from a cloud of gas trapped in the gravitational field of a large number of objects, stars or even neutron stars, bound together by their mutual attraction. Objects like these need not be placed at the distant parts of the Universe. Their production of energy could, for example, be accounted for by interactions between the stars which they include, which in turn implies a structure dense enough for interactions between them to be frequent.

This, however, is only one of many possibilities. Other suggestions have been based on the observation that the radiation from quasars may fluctuate rapidly in a comparatively short time. There is no doubt that, in these circumstances, the region in which the fluctuation occurs must be small by astronomical standards. The size of the region from which the radiation comes must, indeed, be less than the distance travelled by light in the time in which the fluctuations occur. This implies that the sizes of those regions of space responsible for the emission of radiation must be measured in light years or even light days, or that their size lies between 1,000 million km and perhaps 100 times as much. These distances are comparable with the dimensions of the Solar System and are, of course, much smaller than those of the nebulae. The rapidity of the optical variation of the quasar 3C 446 led Cannon and Penston<sup>8</sup> to suggest that the energy comes from a small central source radiating energy at a more or less constant rate, and that clouds of gas would from time to time prevent the escape of the radiation. This view is consistent enough with the argument that quasars should be small objects. The trouble, however, is that if the clouds of gas which obscure the radiation from the central source are moving with the comparatively small velocities which observation suggests are also necessary, the clouds will have to be placed about as far from the central object as the Earth is from the Sun, which will in turn enormously exaggerate the problem of explaining how it is possible for such an object to radiate energy at a rate calculated by Burbidge<sup>9</sup> to be such that each  $\text{cm}^3$  of space around the quasar would contain roughly two Joules of energy. In conditions like that the radiation would be self-destructive, and much of its energy would be carried away by electrons accelerated by the inverse of the Compton effect.

One way out of the difficulty of explaining how quasars can seem at once small and exceedingly energetic is the possibility that they may be comparatively transient phenomena. There is, of course, no means of testing such a possibility directly without

waiting a considerable time to see what happens to individual quasars in the course of several years. Recently, however, a group at the Mullard Radio Astronomy Observatory in Cambridge has been able to show that a certain radio source with all the properties of a quasar has no small blue star associated with it<sup>10</sup>. The question naturally arises of whether the optical component of what may at one stage have been a simple quasar is by now burned out. The difficulty with this interpretation, of course, is that it implies that quasars should be comparatively common phenomena.

This exemplifies the perplexing character of the problem of quasars. Time after time it seems as if some bright idea will provide a rational explanation of the radiation from the quasars, and with comparable regularity it turns out that the explanation entails some unacceptable or at least distasteful consequence. Although opinion seems to favour most of all the possibility that quasars are likely to be exceedingly compact nebulae beyond the limits of this Galaxy, that hypothesis has the status of an intelligent guess.

## GEOPHYSICS

## Continental Drift Comes True

By the end of the century it will seem quite remarkable that the doctrine of continental drift, hotly disputed for half a century since Wegener launched it on a sceptical profession, should have been generally accepted as correct in just about half a decade. Yet this is what has happened. Several independent lines of evidence have conspired to make continental drift respectable, and in the process have borne out Wegener's own statement, quoted regretfully in the preface to his book *Die Entstehung der Kontinente und Ozeane* (Vieweg, Braunschweig, 1928), that the question of continental drift would not be decided by the necessarily qualitative arguments of the geologists and the palaeobotanists but only when it was possible to apply some quantitative geophysical argument to the problem. But the past few years have done much more than make continental drift acceptable. They have also provided evidence to show how the drifting apart of the continents is linked with the existence and the activity of the great ocean ridges—the mid-Atlantic ridge, for example. Indeed, the fashionable phrase is no longer continental drift but ocean floor spreading. Evidently the years ahead will be great fun for those who will be concerned to relate phenomena such as earthquakes and even mountain building with the natural forces, not yet clearly understood, which drive the continents apart.

The origin of the most recent wave of controversy about continental drift lies in the work in the early fifties on the permanent magnetization of all kinds of rocks. Before that, even those temperamentally in favour of radical causes had been forced to admit that the topographical, geological and botanical arguments in favour of continental drift could not in themselves be conclusive. Given the lack of a plausible mechanism whereby the continents might be driven along, it was clear that the circumstantial evidence would have to be quite convincing. Palaeomagnetism has made good the earlier deficiencies of the case for continental drift, though it is only within the present decade that those who work on rock magnetism have been agreed that movement of the continents is the best way of accounting for their measurements.

To be fair, the interpretation of the earliest palaeomagnetic measurements was complicated by the co-existence of two anomalies. First, the direction of the permanent magnetization of a rock might differ markedly from the direction of the contemporary magnetic poles, which suggests that the poles have not always been where they seem to be now or, what comes to the same thing, that the land masses have moved, at least by rotation, since they were formed. But the direction of permanent magnetization can also be entirely reversed, which implies a quite unexpected geophysical phenomenon. It is understandable that people should have sought to avoid both sets of unpleasant consequences by asking whether the permanent magnetization of the rocks was really as permanent

as it was assumed to be—a vein of scepticism which has now been worked out. Both field reversals and the movement of land masses are real phenomena. Studies of successions of lava flows, as in Iceland, have made it possible to trace in detail several successive field reversals, and there is now an even more dramatic demonstration of several cycles of field reversal in long cores recovered from oceanic sedimentary deposits by the Lamont Geophysical Observatory, New York.

Using the magnetic data to work out the positions of the land masses in the geological past has necessarily been a more difficult task, however, for this has entailed the matching together of the apparent movement of the poles as seen from several places on the present surface of the Earth, which raises problems of correlating in age rocks in widely separate places. So, in a sense, it is not surprising that even though maps showing how the poles seem to have wandered as seen from one place on the Earth have been drawn for several years, it is only within the past three or four years that these have presented a convincing picture of the past 100 million years or so.

But how, in any case, could the continents move? It seems that the late Sir Arthur Holmes was the first to suggest that there may be convection currents in the mantle of the Earth involving the bodily movement of material on a time scale long enough for plastic flow to be sustained. More recently, Runcorn invoked convection currents as an explanation of continental drift<sup>1</sup>, and put forward a detailed scheme by means of which a small number of convection cells reach down to the base of the mantle. On this view, one possibility would be that material from the mantle would be carried to the surface of the Earth at the mid-oceanic ridges, and that the continents bordering the Atlantic on west and east would then be found at the places where convecting material would be carried downwards again. Although it now seems that mantle deep convection is unlikely because the viscosity of the deep rocks is too great, the complex of theories now coming into its own is intimately bound up with convection currents of some kind.

The great novelty in the past year or two has been the direct study of the consequences of these lateral movements of material in the surface of the Earth. The starting point seems to have been an argument by Dietz<sup>2</sup> that if, indeed, material from the mantle is welling up towards the surface at the mid-ocean ridges, material should be flowing laterally away from the ridges, from which a number of observable consequences follow. Dietz in 1961 drew attention, in particular, to the way in which ocean floor spreading should mean that the ocean floor is geologically young, and, as it happens, much of the confidence now placed in the reality of continental drift stems from accurate dating of sediments and other features associated with the mid-oceanic ridges. Then Dietz also pointed out that if the mid-oceanic ridges are indeed the sites at which

two long ribbons of material from the mantle are being continually extruded on to the ocean floor, and because these rocks have characteristic magnetic properties, it would not be surprising to find that the pattern of magnetic anomalies associated with traverses of the mid-oceanic ridges would have much in common the whole way along. It was not very long before Vacquier and his colleagues found a striking north-south regularity in surveys of magnetic anomalies off the continental shelf of North America. In other words, accurate magnetic surveys capable of showing up variations of field strength of a few gamma (one gamma =  $10^{-5}$  gauss) seemed to yield contour lines running predominantly north-south, or roughly parallel to the mid-Atlantic ridge lying much farther out to sea.

But why, in any case, should there be such pronounced magnetic anomalies over the deep ocean bottoms? By 1963 it was evident that the magnetic field strength could fluctuate by five or six hundred gamma with a few tens of kilometres immediately above the mid-Atlantic ridge. It is hard to account for variations on such a small scale by differences in the composition of material. So may it be that blocks of material on the ocean floor are magnetized in different directions? This was the question which Vine and Matthews<sup>3</sup> asked themselves, and they pointed out that if, indeed, the direction of the magnetic field of the Earth reverses at intervals, then successive stripes of rock on the ocean floor should be magnetized in opposite directions.

The accuracy of this prediction has now been amply confirmed by several groups of workers at the Lamont Geological Observatory, New York. A year ago, for example, Pitman and Heirtzler<sup>4</sup> described the results of several traverses of the Pacific Antarctic Ridge in the South Pacific on which depth and magnetic surveys were carried out. It turns out that both surveys yield patterns which are remarkably symmetrical on both sides of the ocean ridge, and it is possible to determine with surprising clarity the peaks in the magnetic pattern which lie on each side of the oceanic ridge and which correspond to the same condition of the Earth's magnetic field at some epoch in the past.

This is, of course, a remarkable conclusion. What it implies is that by simply driving a ship on a course at right angles to a mid-oceanic ridge, it is possible to recover a magnetic record which represents on one chart both the reversals of the Earth's magnetic field in the geological past and the spreading of the ocean floor. And because the times at which reversals of the Earth's field occurred are now known with considerable

accuracy—there have been 35 reversals of the field in the past ten million years or so—it is possible without recovering samples from the ocean floor to fit a time scale to the process of ocean spreading. Moreover, by following the pattern of magnetic anomalies sufficiently far back in time, it should be possible to go at least some way towards a reconstruction of the lines on which the continents have drifted away from each other in the past hundred million years or so. The conclusions drawn from these arguments have been clinched by palaeological sediments from the Atlantic bottom which have been recovered by Ewing and his collaborators<sup>5,6</sup>; for one thing, these provide a more continuous record of the variation of the Earth's magnetic field than can be obtained from the necessarily intermittent flow of lava on the surface of the Earth. Furthermore, it has been possible to show directly how the date of the sediments on the ocean floor increases steadily away from the centre of an oceanic ridge.

All this amounts to a consistent picture of how the ocean floor is spreading. One way and another, it appears that the rate of spreading can vary between 1 and 5 cm a year from one place to another along a mid-oceanic ridge. These figures agree well with the estimates which have been made by the examination of samples from the ocean floor of the dates on which the submarine rifts began to function. On the whole, it seems as if there have been 250 million years since the beginning of the mid-Atlantic ridge, which would in turn agree well with the geological evidence which suggests that if Europe and Africa have drifted apart from the Americas, the process probably began in the Upper Cretaceous 250 million years ago or thereabouts.

The accompanying diagram shows various estimates by Vogt and Ostengo<sup>7</sup> of the rate of ocean floor spreading along the length of the mid-Atlantic ridge. Rates are calculated, in cm/yr, from the assumption that the whole Atlantic has opened in  $120 \times 10^6$  yr (solid line *a*) and  $240 \times 10^6$  yr (solid line *b*). The open circles represent estimates by the Lamont group based on magnetic reversals. The solid circles are rates of spreading calculated from the ages of the oldest rocks on certain oceanic islands in the Atlantic.

Inevitably, the recognition that ocean floor spreading is a real and measurable phenomenon will prompt many further studies. One obvious need is to learn more about the pattern of convection, and it is possible that seismology or even deep drilling will identify which layers of the outer mantle are involved. Questions will also arise about the formation of crustal material and what Heezen has called "micro-continents" such as the Seychelles. One interesting suggestion already to emerge is that the strange buried islands called guyots which seem like atolls buried some hundreds of metres in the oceans near mid-oceanic ridges may have arisen from volcanic atolls originally near the top of an oceanic ridge which have moved down its slopes under the influence of crustal spreading<sup>7</sup>.

## SPACE RESEARCH

# Rocket Satellites and Research

In the United States, roughly \$5,000 million a year is being spent on space research and development of all kinds and much of it—\$694 million in the current financial year—is devoted to what may be described as research unrelated to practical objectives. It is inevitable that expenditure on this scale should have influenced considerably the pattern of academic research in the United States and elsewhere, and that it should have reaped a rich harvest of data. Although there may be something in the argument that similar benefits could have been won more cheaply in other ways, nobody denies the value of what has been done in the past decade by rockets and satellites. Dr Homer Newell of the National Aeronautics and Space Administration had no need to overstate his case when he applied on behalf of the administration to Congress for funds with which to keep NASA going for another year.

Something of the scale of the operation in support of research being carried out in the United States can be gathered from the numbers of rockets launched under the Space Science and Applications Program in recent years. Since the beginning of the sixties, the numbers of rockets have fluctuated around an average of 14 or 15, and are expected to reach a peak of 20 during the current year. These figures do not include the great numbers of sounding rockets, costing \$22 million a year, launched from the United States for a variety of reasons, often in meteorology.

What have been the results? Dr Newell claimed that the rockets and satellites had provided new tools for the study of old problems in geophysics, had opened up entirely new areas of research such as in the belts of radiation surrounding the Earth, and had for the first time made it possible to study directly the physics of the plants in the Solar System. He went on to suggest that space research would resolve a number of important issues in physics such as the correctness or otherwise of current notions of relativity, and predicted that space techniques would have an equally profound influence on astronomy. The discovery of X-ray stars is the proudest boast in this connexion.

In reality, of course, the discovery of X-ray sources in the sky was made with comparatively simple rockets (in 1962 by Herbert Friedman) at the Naval Research Laboratory in Washington. The first sources to be recognized were in Scorpio, Cygnus and Taurus. Altogether more than 20 X-ray sources are now known. They lie in the plane of the Milky Way, which implies that they belong to the galaxy. (The external galaxy M87 also emits X-rays.) Occultation of the X-ray sources by the Moon has shown that they are not starlike, but, rather, distributed. Some are now known to be old novae. Dr Newell in his evidence pointed out that a great deal of work had been carried out with

sounding rockets provided by NASA. By now, of course, other agencies elsewhere in the United States are using rockets like these for the study of X-ray sources.

X-rays from the Sun are another feather in NASA's cap, although these were first discovered a decade ago before the space agency had been established and when the US Navy was supporting the research directly from its own funds. In recent years photographing of the Sun with X-ray plates carried in rockets has become sufficiently a matter of routine for useful correlations to be made between X-ray emission and other features of the solar surface—sunspots, for example. One part of the programme being planned for and carried out consists of the orbiting solar observatories intended to carry large packages of instruments into long-lasting orbits about the Earth. But NASA is also planning what are called orbiting telescopes—devices which will be in part optical telescopes and in part radiotelescopes of various kinds.

The exploration of the Solar System has been undertaken largely with the help of long-ranging rockets launched from the Earth. As yet, however, it does appear that the data gathered by the Mariner II flight past Venus did not produce conclusive results about the constitution of the atmosphere of the planet. Rocket engineers are not the ones to blame for this. There is such a wide range of models for the atmosphere of Venus, and such a variety of estimates of the thickness of the atmosphere, that it seems that rocketry will not be able to contribute much more than conventional forms of astronomy at least until it is possible to launch rockets into orbits about Venus.

NASA's contribution to the understanding of Mars depends on the flights of rockets past the planet, the first of these in 1965 at a distance of 4,000 miles. This has produced photographs with a resolution of roughly two miles. It will be interesting to see how quickly the budgetary pressures to which it is now being subjected will be eased to the point at which NASA will be able to use larger Saturn rockets for launching their ambitious devices towards Mars. One way and another, it seems that NASA hopes its contribution to the accurate description of the planets lies in the future—possibly the comparatively near future.

In its evidence to Congress, however, NASA can make a strong case for the value of its work in throwing light on the region called the magnetosphere around the Earth in which the Earth's magnetic field is a dominating influence, and on the interaction between this region and the flux of atomic particles from the Sun which is called the Solar Wind. The magnetosphere as such is by now, of course, an ancient concept. It has been a feature of a great many theories to explain such

phenomena as the variation of the strength of the Earth's magnetic field as observed on the ground with activity on the surface of the Sun. But van Allen in 1957 discovered that atomic particles, protons and electrons, are trapped by the magnetic field of the Earth. In the years since then, a great many space rockets have been able to map out not merely the average shape of the trapped radiation but also have been able to describe its variation from one time to another. But the Solar Wind is something else again—nothing was known of it but some speculation before 1958. It consists of electrified particles travelling outwards from the Sun with speeds of 300 and 700 kilometres a second when they cross the orbit of the Earth. The Solar Wind has something between 3 and 60 protons in each cubic centimetre. Because of the rotation of the Sun, it sweeps out in a spiral fashion which is evident enough now that rockets are able to chart the directions in which the Solar Wind appears to be moving with considerable precision.

The interaction between the magnetosphere and the Solar Wind is by now familiar; the speed of the outward moving stream of particles is supersonic in the medium, which in turn implies the formation of a shock wave at the outer boundary of the magnetosphere. In practice, the existence of the Earth's magnetic field provides a means of warding off the Solar Wind, which instead sweeps back behind the Earth to leave a wake or shadow stretching backwards for perhaps several hundred Earth radii. So much at least is apparent from the record of the flight of the rocket Pioneer VII launched in the autumn of 1966. Plainly, until more is known about the balance of forces within the Solar Wind and the magnetosphere, rockets will play an indispensable part in the delineation of its properties.

There remains the contribution which NASA and its works have made to the understanding of the atmosphere of the Earth. As soon as the first satellites appeared a decade ago it was clear that their motion would be markedly influenced by such things as the density in the high layers of the atmosphere. The first suggestion that the density above 100 kilometres was greater than had first been expected has now been followed by the recognition that temperature increases more rapidly than had been thought, at least in the first 200 kilometres above the Earth. Thereafter, and out to whatever may be the limits of the atmosphere, the temperature remains substantially constant, but at a value which may vary between 1,000° C and 1,500° C according to the activity of the Sun.

Dr Newell is entirely right to claim, as he does, that NASA has contributed directly to the spate of discovery by rockets and satellites which have been launched from the United States in the past decade. Satellites such as Explorer IX (1961), which consisted of a sphere 12 feet across, were designed deliberately as a means of measuring atmospheric density. Explorer XVII (1962) carried mass spectrometers for the first time, and the use of those instruments confirmed an earlier suggestion by Nicolet that there is a layer of the atmosphere in which helium predominates above 1,000 kilometres. More recently, NASA has been launching much heavier satellites such as the orbiting geophysical observatories, the first of which appeared in 1964, and the similar devices intended to carry out astronomical work. Devices like these will consume

an increasing share of the budget which NASA has to spend on space research. In the present financial year, for example, \$20 million will be spent on orbiting geophysical satellites to be launched at various times in the next five years, and \$40 million on astronomical observatories. NASA itself would not wish to deny how much uncovenanted use has been made of its rockets and satellites in the past decade—it remains a striking fact that some of the most interesting studies of such things as the variation of the density of the upper atmosphere from one time to another have been made by people not directly concerned with the design of experiments for inclusion in satellites. There are some circumstances when access even to such rudimentary information as the orbital elements of satellites can be of value in throwing light on the character of the upper atmosphere.

In the years ahead, it is plain that NASA's scientific programme—the enterprise to carry men to the Moon comes under another heading in the budget—will be increasingly concerned with matters such as the despatch of rockets towards the planets and the Moon. There is, for example, the Voyager programme as a part of which rockets will be sent into orbits around Mars and Venus or landed without damage on the planets. The first flight of such a rocket will be towards Mars in 1973, and it is a striking commentary on the length of time over which plans for space research must be laid that the design of the Voyager satellites will consume several million dollars in the current financial year. By means of these programmes it is hoped that it will be possible to land packages of instruments weighing up to half a ton on the surfaces of the planets Mars and Venus so as to continue there the kind of work at present being done or to be attempted in the next few years on the surface of the Moon. Between now and 1973, however, NASA will use less sophisticated means of sending rockets to Mars and Venus under the heading of what is called the Mariner programme, by means of which it has already been possible to gather important information about the character of the atmosphere of Venus. Photographs of the surface of Mars have come out of the same Mariner programme.

Not all the new plans will cost enormous sums of money, however. There is, for example, an imaginative scheme designed by a group at the Massachusetts Institute of Technology intended to use the comparatively cheap Scout rocket for sending instruments into an orbit about the Sun. The first launchings of these devices may be made in 1968. Before then, at least two more Earth satellites intended to gather information about the Sun will have been put into orbits, and it is intended to use these devices to keep a continuous and detailed watch on the Sun during the period of maximum solar activity in 1969.

One feature of the NASA plan which will not be much welcomed in the universities is the way in which the growing pressure on the budget as a whole—and particularly the pressure to reduce the cost of sending men to the Moon—has forced a reduction of the amounts of money being allocated to the support of university programmes in the United States. Training grants in the present financial year are down to less than a third of what they were two years ago. NASA will spend \$20 million on the support of work in universities in the year ahead, which is less than a half of its expenditure two years ago.

## MOLECULAR STRUCTURE

# How One RNA Molecule is Strung Together

It is now almost a matter of routine to work out how the amino-acids in a protein molecule are arranged along its length—and there are even machines which are said to do the job automatically<sup>1</sup>. Working out the arrangement of units along the length of a nucleic acid molecule is much more difficult for several reasons. For one thing, in a protein molecule there may be up to twenty different amino-acids, many of which are easily distinguishable from the others; in nucleic acids such as DNA or RNA, by contrast, there are usually only four possible different units from which chain-like molecules may be assembled, which means that if a molecule is broken chemically into smaller pieces, these may be difficult to tell apart. One consequence is that the structures of all but the smallest and simplest molecules of nucleic acids have so far been inaccessible except by inference.

This is why it is an important landmark in molecular biology that Dr F. Sanger and his colleagues<sup>2</sup> at the MRC Laboratory of Molecular Biology at Cambridge have been able to work out the sequence in which no fewer than 120 sub-units are arranged in a particular molecule of RNA. Their work carries significantly further the work of Holley and his collaborators<sup>3</sup>, who showed two years ago how to obtain the sequence of sub-units of a molecule of RNA half the size of that which has now been analysed but in which the occurrence of certain easily distinguished and unusual units served to simplify the problem.

The material which Sanger and his colleagues have used is interesting in its own right, for they have chosen for their chemical analysis a molecule of RNA which is a functional component of the molecular apparatus for manufacturing protein in the bacterium *Escherichia coli*—the workhorse of molecular biology. Specifically, the molecule is the smallest of the three nucleic acid components of the ribosomes at which protein molecules are assembled from amino-acids. Altogether it consists of no fewer than 120 sub-units strung together.

The technique used for this complicated analysis will undoubtedly be widely used in the years ahead. So as to be able to work with extremely small quantities of the RNA, Sanger and his colleagues have used material in which the nucleotide units in the chain—there are four kinds of them altogether—are heavily laden with radioactive phosphorus-32. The next step is that already used in the analysis of simpler RNA molecules—they are broken into smaller pieces by treatment with forms of the enzyme ribonuclease which have the effect of consistently breaking the RNA molecule at the links between specific pairs of nucleotides in the chain. The various fragments have been separated from each other by various forms of chromatography which yield a two-dimensional pattern of spots on a piece of filter paper, each spot being recognized by its radioactivity and characteristic of some fragment of the whole molecule. An essential part of the job has been to find ways of incompletely breaking

down the RNA molecule by partial digestion with ribonuclease so as to be able to decide how the smallest fragments are linked together.

In many ways the whole procedure is closely analogous to the now standard methods used for working out the arrangement of amino-acid units in the long chains of protein molecules, and it is, of course, more than just a coincidence that Sanger played a central part in the development of those more than a decade ago.

The outcome of this analysis is embodied in the accompanying diagram. The symbols A, C, G and U stand for the four nucleotides adenine, cytidine, guanine and uridine which can be linked together to form molecules of RNA. The direction in which the units are strung together is identified by the chemical symbols for phosphorus and hydroxyl which appear at one or other of the two ends. The chemical analysis by itself provides only the order in which the nucleotide units are arranged along the chain, but it can be inferred from this sequence that the molecule has three separate regions which are cross linked by hydrogen bonding. In these regions the character of the nucleotides is such that they will of their own accord coil into the spirals analogous to those in a DNA molecule.

Sanger himself has pointed out that substantial sections of the molecule repeat each other—the sections beginning with the units numbered 10 and 61, for example—and he suggests that this may have an evolutionary significance. At one time there may have been organisms in which the corresponding RNA molecules were only half the size. But it may also be

(Continued on page 1067)

## PROTEIN STRUCTURE

# Structure and Function of Proteins

THE past few months have brought a rich harvest for those concerned with the three-dimensional structure of protein molecules. Within a few weeks, earlier this year, structures were obtained by X-ray diffraction for several important molecules—the enzyme ribonuclease (in two versions) and the enzyme chymotrypsin. And there is the promise of similar information about other enzyme molecules soon to come.

The interest of this work is two-fold. It is important to know why large protein molecules, with 100, 200 or more amino-acid units strung together in a chain, should consistently form themselves always into the same specific three-dimensional pattern. What is it about the chemical constitution of a protein molecule that determines what its overall shape should be? But there are more practical reasons than these for hoping for a great deal from the detailed information now accumulating. In particular there is at least a sporting chance that detailed structures of some enzyme molecules will help to explain how these molecules function in real life.

At the beginning of this year, only the structures of myoglobin and lysozyme were known with such detail that the positions of individual atoms in a three-dimensional structure could be placed with certainty. (A good deal is also known about the three-dimensional structure of the haemoglobin molecule in various stages of its combination with oxygen.) Molecular structures can be obtained for protein molecules by X-ray diffraction only when crystalline forms of them can be prepared. To give the molecules characteristics which can easily be identified in the X-ray diffraction patterns, it is necessary somehow to prepare crystalline derivatives in which heavy atoms such as mercury are associated with the molecules almost as if in a chemical combination. The technique for carrying out this kind of analysis was first developed at the Cavendish Laboratory, Cambridge, by Dr M. F. Perutz and, later, by Dr J. C. Kendrew.

The X-ray analysis of the ribonuclease structure may be of especial value in working out a relationship between structure because of the detailed chemical studies which have already been carried out. Altogether there are 124 amino-acid units in the protein chain, and the chemical properties of the molecule indicate that the chain is folded in such a way that it is linked internally at four places.

But ribonuclease is also important because of its biochemical function—it is a means by which nucleic acids are hydrolysed *in vivo* and *in vitro*. Obviously there is great interest in the details of precisely how it functions.

In March, Carlisle and his colleagues<sup>1</sup> described a structure for ribonuclease *A* at the comparatively low resolution of 5.5 Å. This was closely followed by the publication of a structure at 2 Å resolution by Harker and his colleagues<sup>2</sup>, and by Wyckoff and Richards' announcement<sup>3</sup> of a molecular structure, at 3.5 Å resolu-

tion, of ribonuclease *S*—a derivative of ribonuclease *A* produced by subtilisin. The degree of agreement between the structures proposed by Harker's group and by Wyckoff and Richards is gratifying, especially because the two groups used different heavy atom substitution derivatives and different solvents. Further, the differences between the Harker and Carlisle structures, which arose from differences of interpretation rather than of data, have now been reconciled.

The polypeptide chain of ribonuclease *A* is folded to form a more or less kidney-shaped molecule, 38 × 28 × 22 Å, with a deep cleft in the centre. On either side of the cleft the loops of the polypeptide chain are linked together by chemical bridges, and there is a short segment of the protein molecule standing apart from the rest of the molecules, and overhanging the cleft.

What is the chance of relating this three-dimensional structure to the biochemistry of ribonuclease? By chemical studies, the two American groups have been able to show that the cleft of the molecule is indeed the site of the activity of the enzyme, where there is now seen to be a cluster of groups derived from the amino-acids lysine and histidine. These units in the long protein chain seem to be intimately involved in the functioning of the enzyme—for example, they are equipped with side chains which can combine with materials which inhibit the enzyme, presumably by filling up the cleft of the molecule with inactive chemical groups.

All this agrees well with chemical evidence collected much earlier, and which had always been hard to understand in the absence of a three-dimensional structure of the molecule. For one thing, it was clear that two histidine residues near the opposite ends of the protein chain are both a part of the active centre<sup>4</sup>, which implies that the molecule is somehow wrapped up on itself. Hirs<sup>5</sup> showed that a lysine group a third of the way along the chain is essential to the enzyme activity. How could such widely separate parts of the molecule be simultaneously involved? That is a question that the biochemists were forced to ask themselves. It now emerges that the two histidine groups are close together on one side of the cleft in the molecule, and that the lysine group is placed directly opposite.

These correlations are comforting, but they are only the beginning of a full explanation of how the enzyme molecule functions. One of the difficulties with ribonuclease is that it has not yet been possible to make a crystalline form free from extraneous chemical groups attached to the active site. There has been more success with lysozyme, which also has a cleft in the otherwise blob-like shape into which the protein chain is wrapped, for there it has been possible to follow the changes of shape which occur when the enzyme molecule associates with molecules of substrate or inhibitor. In the long run, the objective will be to understand

how the parts of enzyme molecules remote from the active sites somehow play a part in enzyme function.

The shapes of protein molecules will not easily be understood in detail, but a few general principles seem to have emerged from a comparison of all the X-ray structures now available. One of the structures most recently to have been determined—that of chymotrypsin—resembles the structure of molecules such as lysozyme in that the long protein chain is curled up in such a way that the amino-acid groups which are chemically hydrophobic tend to be buried within the molecule. By contrast, hydrophilic groups lie on the outer surface. That is reasonable enough, although it does raise the question of how the shape of a protein molecule is influenced by such things as the acidity of the medium. It will also at some stage be important to know why the structure of chymotrypsin differs from that of most of the other proteins so far mapped in detail in that only a very small part of the chain is coiled into the helical form which protein molecules tend naturally to form.

What lies ahead? To begin with, the structures of more protein molecules will be determined, and it is only seemly to remember that a full-scale X-ray analysis is still a tedious and even an uncertain venture. That said, detailed structures of the protein antibody molecules would clearly be of the greatest interest now that the chemistry of these materials is being understood. And for the rest it is abundantly clear that the X-ray structures of protein molecules which have appeared in the past few months are not an end point in themselves but only incentives for other investigations.

## CELL BIOLOGY

# Synthesis of an Enzyme

Nirenberg and Matthaei provided an invaluable method for the investigation of protein synthesis when they discovered that in cell free systems—essentially the pulp of ground-up cells containing ribosomes, transfer RNA and other components necessary for protein synthesis together with an added source of energy—peptide bond formation occurs and amino-acids are incorporated into polypeptides under the direction of endogenous or added messenger RNA. As a result, cell free systems have been increasingly used for studies of protein synthesis *in vitro* and they have yielded otherwise unobtainable data. But there has always been a nagging doubt that since the conditions in a cell synthesizing protein are so different from those in a test-tube, what occurs *in vitro* in a cell free system may not occur *in vivo* within the cell. Such doubts were not diminished when it was found that in a cell free system programmed with a particular messenger RNA, the amino-acids incorporated into polypeptides vary with the ionic environment and especially with the concentration of  $Mg^{++}$  ions.

It was something of a relief, therefore, when it was shown that haemoglobin and some RNA phage proteins synthesized *in vitro* have a similar peptide composition to the natural proteins. Unfortunately, however, these proteins are not enzymes; they cannot be assayed for biological activity and so the fidelity of *in vitro* protein synthesis cannot be properly assayed. It is quite possible that even if a protein synthesized *in vitro* had the same amino-acid sequence as the natural product, it could not, in the artificial environment of a test-tube, fold to assume the secondary and tertiary structures which determine its biological activity. Hence the recent demonstration by Salser, Gesteland and Bolle (*Nature*, **215**, 588; 1967) of *in vitro* synthesis of biologically active  $T_4$  bacteriophage lysozyme assumes a double importance. Apart from providing an experimental system for precisely defining the components and conditions necessary for synthesis of an active enzyme their result raises the general level of confidence that can be placed in *in vitro* observations.

$T_4$  lysozyme, an enzyme made by the phage fairly late in the infection cycle, causes the dissolution of the bacterial cell wall and the release of the progeny particles. It has several obvious advantages for study *in vitro*. There is a very sensitive assay for it; it consists of a single polypeptide chain and is a fairly small protein (molecular weight 18,000) and so must be coded for by a small messenger RNA molecule. This is important because it increases the chances of isolating the messenger RNA undegraded.

Salser *et al.* isolated the RNA made in phage infected *E. coli* and used this to programme a cell free system. The protein made was assayed for lysozyme and showed activity. Moreover the amount of lysozyme made *in vitro*, about 4 per cent of the total protein synthesized, is similar to the amount made *in vivo*. Several controls showed the enzyme had been made *de novo*. For example, RNA from cells infected with a mutant phage that lacks the gene for lysozyme failed to stimulate lysozyme synthesis *in vitro*, and puromycin and chloramphenicol, drugs that inhibit protein synthesis *in vivo*, abolished the *in vitro* synthesis of lysozyme.

It is clear from these experiments that in the environment of a cell free system, the translation of the information encoded in RNA into the sequence of amino-acids in a protein can be sufficiently accurate to yield an active enzyme.

(Continued from page 1065)

that this symmetry has something to do with the geometry of the ribosomes from which the RNA molecule has been derived<sup>1</sup>. Another feature of the shape of the molecule to which Sanger has drawn attention is the occurrence of internal regions in which the molecule is coiled into a spiral form. In this respect the long RNA molecule has something in common with the structure of the smaller molecules of what is called transfer RNA first worked out by Holley and his collaborators, the function of which seems to be to involve individual amino-acid molecules in the construction of a protein.

## CYTOLOGY

# Organization of Chromosomes

As the genetic code is solved in more and more detail the organization of the genes on the chromosome is also being closely attended to. A model proposed by Callan<sup>1</sup> involves serially repeated nucleotides, or gene copies, which form a terminal master gene with a number of slave genes. This model helps to explain the behaviour of some chromosomes during the reduction division—meiosis—which involves recombination between chromosomes and gives rise to the haploid gametes of diploid organisms.

Cytological evidence shows a very wide variation in the content of DNA—together with protein, the raw material of chromosomes—in the nuclei of gametes of related diploid organisms. This would be explained if chromosomes were multistranded—that is, if they contained several parallel DNA fibres—for some could then contain more fibres than others. This, however, seems unlikely on genetical evidence; multistrandedness does not fit in with semi-conservative DNA replication or with the phenomena of mutation and recombination, all reliably demonstrated long ago. This dissimilarity of DNA content is much more acceptably explained in the light of Keyl's observations<sup>2,3</sup> of the salivary gland chromosomes of *Chironomus*, a midge. He found that the ratios of DNA contents in homologous bands on the chromosomes conformed to a geometric doubling series 1 : 2, 4, 8 and 16. Keyl<sup>4</sup> has shown that this is not the result of unequal DNA replication in different bands, and the explanation seems to be that there is a serial replication of genetic units along a chromosome, different amounts of duplication leading to more or less DNA in a chromosome.

Callan<sup>1</sup> developed this idea to propose that each chromosome may have several copies of the same gene of which the terminal one, by virtue of its position, acts as the master gene while the others are slaves. This would explain Callan's own observations of the loops on lampbrush chromosomes of amphibian oocytes. The formation and regression of these loops in different places along the chromosome can be explained if after recombination between chromatids of homologous chromosomes, restricted to the master genes, the nucleotide chains of the slave genes are matched with those of the master gene, so that the slave nucleotides come to lie adjacent to those of the master. If necessary slave nucleotides are corrected so that their nucleotide sequences conform with those of the master. Each slave sequence is matched in turn, and the uncoiling involved would produce the loops which are observed. Only slave genes would act as templates for DNA synthesis, which would occur while they are exposed in the loop. This agrees with the known function of the loops, to produce ribonucleoprotein.

Whitehouse<sup>5</sup> has pointed out that the necessary separation of neighbouring master genes does not conform with data on recombination in *Aspergillus*

*nidulans* which imply the presence of only one copy of each master gene, each of which must be in contact with its neighbours. To reconcile this disparity Whitehouse has modified Callan's model and suggests that during meiosis, slave genes are removed from the chromatid by a crossover between the first and last members of the linear series of identical genes. While detached from their chromatid the gene copies are in the form of a closed circle. After crossing over has occurred between homologous chromatids the gene copies are replaced in their chromatid by the same mechanism by which they were removed. In a further modification of Callan's model, he suggests that only one nucleotide chain of a slave gene—the one which is a template for RNA synthesis—is matched to the master gene. Matching would always occur before the slaves function as templates.

This model now has to be tested experimentally. Hotta and Bassel<sup>6</sup>, for example, have electron microscope evidence that part of the DNA of the sperm of the boar, *Sus domesticus*, is circular, and some amphibian nucleoli have been shown to contain circular DNA<sup>7</sup>. Other such evidence should not be difficult to obtain. Chromosomes could be examined, by electron microscopy and special staining techniques, during the reduction division of meiosis, and this might reveal circular DNA molecules in all kinds of organisms. Similar investigations might also give more information about the proposed matching of master to slave in the amphibian lampbrush chromosomes. Further information about the part of these chromosomes which is responsible for the production of the nucleolus, and which is known to replicate many times and produce rings of DNA, could also be obtained. Reliable results from work such as this could be very instructive in substantiating this model for the organization of chromosomes, which is as yet very speculative.

This is an attractive model; it accounts for a variety of apparently contradictory genetical and cytological data. Fincham<sup>8</sup> has used it to account for the almost continuously graded variation of derivatives of mutable genes—genes which show a much higher frequency of mutation than is usual. As a result of a mutation in the master gene the linear gene series becomes internally heterozygous, for the slaves remain normal. The instability characteristic of mutable genes would be provided by the replacement of defective nucleotides in a master by normal nucleotides from a slave, and this could be brought about by intrachromosomal crossing over and/or correction of master by slave.

## ECOLOGY

## Intense Selections and the Speed of Evolution

THE Darwinian theory of organic evolution is so widely accepted that it is easy to forget that the direct evidence for it is limited to a few cases in which evolution has been studied in the wild. Perhaps the best known of these is that of the peppered moth, *Biston betularia*, whose black form has become abundant in Britain since the Industrial Revolution.

It had been thought that advantageous characters only slightly increased the viability of an animal; selective advantage was low, and evolution invariably slow. Recent work has shown that this assumption was unjustified. A common British butterfly of grassland, the meadow brown, *Maniola jurtina*, bears a series of spots on the underside of its wing. The number of spots, which is controlled by many genes, varies from none to five. A team of workers led by Ford<sup>1</sup> discovered that the distribution of spot frequencies for female butterflies remained strikingly constant over most of England, despite great differences in climate. In south-west England, however, the spot frequency distribution was different, and a larger number of insects had two spots. At the boundary of these two areas one would have expected populations with intermediate spot-frequency distributions, and a gradual transition between the two main types of distribution over, perhaps, tens of miles. Instead, the boundary line was found to be a hedge, over which insects were flying freely.

This combination of stability over a huge area, and sudden transition to an alternative distribution, is a result of very high selection pressures. This has been confirmed by work in the Isles of Scilly, where each island is characterized by a particular spot-frequency distribution of *Maniola*. Great changes in spot-frequency distribution have been seen to take place within a year in association with ecological changes. On the other hand, under constant ecological conditions, when the population of *Maniola* was reduced to a few hundred individuals, in the next generation the population had regained not only a considerable size but also its characteristic spot distribution. The selection had been strong enough to overcome chance effects acting on the reduced population, such as the "accidental" death of insects possessing advantageous genes. It has been calculated that as many as 80 or 90 per cent of animals of certain spot-numbers may be selectively eliminated within a few months.

It is most unlikely that this very high death rate is caused by the spots themselves. The genes which produce the spots must be responsible for more important characters. Work is going on to discover what these are<sup>2</sup>. It has been shown that animals with more spots are susceptible, in some unknown way, to the attacks of a parasitic insect, *Apanteles*. There is also a possibility that the bacteria in the intestines of *Maniola* may be concerned with the selection against certain forms.

A similar situation has recently been shown to exist in populations of a grass, *Agrostis tenuis*<sup>3,4</sup>. This plant has various forms characterized by their hardiness in particular climatic or chemical conditions. Some are able, for example, to survive in windy conditions, or in the face of sea spray, or where the soil concentration of metals is high. These conditions may change over a few yards, as where slag from a mine has been heaped up in a field where the soil has not been contaminated by metal. Because of the very high selective pressures acting to eliminate forms which are inviable in the particular microhabitat, adjacent small populations of *Agrostis* consist of very different forms, even though there is cross pollination between the two populations. In this case, then, strong disruptive selection opposes and overcomes the effects of gene flow.

Another example of rapid evolution was investigated by Dobzhansky and Pavlovsky in California<sup>1</sup>. One of the chromosomes of the fruit fly, *Drosophila pseudoobscura*, is marked by the reversal of the genetic material at one point. Many such inversions, as they are called, appear in the chromosomes of this species, this one being known as Pike's Peak (P.P.). In the 1940s the frequency of this inversion was so low that it was effectively absent in California. Since then, however, there has been a rapid increase in the percentage of animals bearing the inversion, and a corresponding decrease in the percentage of animals bearing another important inversion. This major change in the genetic configuration of the species does not seem to have been a product of any gross meteorological change. Yet an increase in the frequency of P.P. has taken place in areas of the state with very different climates. Nor is the phenomenon associated with towns or industries; there seem to be no obvious differences between populations in country and town. Migration cannot explain the phenomenon, and it is unlikely that increased radiation levels are its cause. And it is a mystery not only why the increase came about, but how the P.P. inversion has become prevalent throughout so vast a space in so short a time.

It was long ago pointed out by Ford that evolution is most rapid, and can be most easily studied, when populations are small, when there exist two or more forms of the same species within the same habitat, or when the selective advantage of a character is great. It now appears that these conditions are fulfilled more often than had been supposed. It is therefore necessary to revise views of the speed of evolution and of the part which selection plays. Selection has always been thought to have been important, but in many cases it may be overwhelmingly so.

## MOLECULAR BIOLOGY

## Isolation of Genetic Repressors

IN such a rapidly expanding and fiercely competitive field as molecular biology, comparisons are bound to be invidious, but few would deny that the outstanding achievements in the past 12 months have been the isolation of two repressors and the consequent confirmation of Jacob and Monod's model of genetic regulation.

A brilliant series of deductions led Jacob and Monod from their kinetic data on enzyme induction in *E. coli* to the operon concept and to a model of genetic regulation in which operon-specific repressor molecules prevent the expression of sets of genetic information—the operons—until these are required by the cell. The classic example is the negative control of the lactose operon which envisages a repressor molecule preventing the expression of three genes involved in lactose metabolism, until the inducer, normally lactose, is presented to the cell, whereupon the genes are derepressed, enzymes are made and the lactose metabolized. The simplest hypothesis to account for the action of inducer and repressor proposes that the repressor actually binds to the DNA, preventing transcription, and that the inducer by binding to the repressor somehow modifies it, perhaps by allosteric changes, so that it can no longer bind to the DNA.

Confirmation of this hypothesis, which has become central to much of molecular biology, awaited the isolation of a repressor molecule and there was understandably great excitement when Gilbert and Müller-Hill announced (*Proc. US Nat. Acad. Sci.*, **56**, 1891; 1966) that this had been done for the lactose operon repressor. The approach was elegant and direct, based on the minimal assumption that repressor and inducer interact. Gilbert and Müller-Hill reasoned that because an uninduced *E. coli* must contain some lactose repressor molecules, it should be possible to isolate them simply by fractionating the total cell protein. That done, the repressor fraction could be identified by its ability to bind inducer specifically and reversibly. The isolation of suppressible amber mutants of repressor genes had already shown that repressors are proteins, not nucleic acids. Gilbert and Müller-Hill made cell extracts of a mutant strain of *E. coli* with a lactose repressor which appeared to bind inducer more tightly than wild-type repressor, and after a crude fractionation they dialysed the fractions against a radioactive inducer, not lactose but an analogue. With minds sharpened by many months of negative results, they immediately grasped the significance of one fraction which bound inducer very slightly more than all the others above the background level. Further fractionation of this material yielded the repressor.

Two other mutant strains provided negative controls. First, Gilbert and Müller-Hill could not detect binding between their inducer and fractions from a strain of *E. coli* which always makes the lactose enzymes even in the absence of lactose. These cells evidently lack

the repressor. Second, all the fractions from a mutant strain which has a modified repressor molecule and is not induced *in vivo* by the inducer they were using failed to bind the same inducer.

The lactose repressor has a sedimentation coefficient of 7 to 8S, and an estimated molecular weight of 150,000 to 200,000. It is a rather large protein. Gilbert and Müller-Hill also estimated that the repressor corresponds to only about one part in  $10^4$  of the total cellular protein. This gives an indication of the magnitude of their achievement in isolating it.

Closely following this success, Ptashne (*Proc. US Nat. Acad. Sci.*, **57**, 306; 1967), from the same Harvard laboratory, isolated the  $\lambda$  phage repressor which is responsible for completely repressing the entire phage genome, allowing the establishment of lysogeny, and for the immunity of lysogenic bacteria to super-infection. By taking advantage of a strain of *E. coli* which can, after massive ultra-violet irradiation, maintain phage protein synthesis even though its own protein synthesis is greatly reduced, and by making use of super-infection immunity, Ptashne isolated the  $\lambda$  repressor using column chromatography and a double-labelling technique. He identified the repressor fraction as such by showing that it is not made by  $\lambda$  phage with an amber mutation in the repressor gene and that phage with a temperature sensitive mutation in this gene make a modified form. The  $\lambda$  repressor is an acidic protein and, with a sedimentation coefficient of 2.8S and an estimated molecular weight of 30,000, it is much smaller than the lactose repressor.

Ptashne has gone on to show that the  $\lambda$  repressor does indeed bind to DNA (*Nature*, **214**, 232; 1967). A phage known as  $\lambda$  imm<sup>434</sup> lacks a small region of the wild-type genome including both the repressor gene itself and the site which determines the sensitivity of the phage to  $\lambda$  repressor. In other words,  $\lambda$  imm<sup>434</sup> neither makes  $\lambda$  repressor nor is repressed by it. The protein Ptashne had isolated and identified as the  $\lambda$  repressor binds to  $\lambda$  DNA but not to  $\lambda$  imm<sup>434</sup> DNA. This simple experiment not only proves that the isolated protein is in fact the specific repressor but also strongly suggests that the repressor acts by binding directly to DNA and thus preventing transcription. Further support for this conclusion comes from Gilbert and Müller-Hill's demonstration that the lactose repressor binds to lactose operon DNA and moreover can be removed from the DNA by an inducer. Neither of these observations, of course, proves that the binding of repressor to DNA prevents transcription, but Gilbert and Müller-Hill are now in a position to show this unambiguously with *in vitro* experiments.

There is no doubt that this important work has opened the way to a complete elucidation of the molecular events that occur during genetic repression and induction.

(Continued from page 1054)

the untreated surface used by Barbarisi is typical of polyethylene and that the treatments given increase  $\gamma_c$  above the literature value of  $\gamma_c = 31$  dyne/cm.

Fowkes<sup>4</sup> has shown that the angle of contact is related to the dispersion force contributions,  $\gamma_s^d$  and  $\gamma_{LV}^d$ , to the surface tensions of solid and liquid

$$\cos \theta = \frac{2(\gamma_s^d \gamma_{LV}^d)^{1/2}}{\gamma_{LV}} - \frac{\pi}{\gamma_{LV}} - 1 \quad (3)$$

where  $\pi$  is the spreading pressure (Zisman has shown that for low energy surfaces  $\pi \approx 0$  if  $\theta > 0$ ). For the epoxy-polyamide adhesive used by Barbarisi  $\gamma_{LV} = 41.7$  dyne/cm. Equation (3) can therefore be used to calculate the expected contact angle for the adhesive on polyethylene, provided  $\gamma_{LV}^d$  can be obtained. The maximum value of  $\gamma_{LV}^d$  is  $\gamma_{LV}$ , and on the basis of comparison with the contribution of  $\gamma_{LV}^d$  to  $\gamma_{LV}$  of other organic liquids<sup>4</sup>, a minimum value of about  $0.75 \gamma_{LV}$  or 30 dyne/cm is reasonable. When  $\gamma_{LV} = \gamma_{LV}^d = 41.7$  dyne/cm, equation (3) gives  $\theta = 33.3^\circ$  and, when  $\gamma_{LV}^d = 30$  dyne/cm,  $\theta = 56.6^\circ$ . The values of  $\theta$  given by Barbarisi are  $35.4^\circ$  on untreated polyethylene and  $18.5^\circ$  on polyethylene wiped with acetone and treated with acid (unknown) for 5 min at  $70^\circ$ . The untreated surface therefore most resembles polyethylene—a conclusion reached without invoking the concept of  $\gamma_c$ .

The empirical linear relation found by Zisman and co-workers<sup>3</sup> can be written as

$$\cos \theta = 1 + b\gamma_c - b\gamma_{LV} \quad (4)$$

where  $-b$  is the slope of  $\cos \theta$  against  $\gamma_{LV}$  plots;  $\gamma_c$  will equal  $\gamma_{LV}$  when  $\theta = 0$ . This shows that the contact angle exhibited by a given liquid on different solids will depend on  $b$  as well as on  $\gamma_c$ . Equation (4) can be used to estimate the surface tension of a liquid which gives  $\theta = 35.4^\circ$  on polyethylene, for Zisman<sup>3</sup> established that  $b = 0.026$ . The result,  $\gamma_{LV} = 38.1$  dyne/cm, compares favourably with  $\gamma_{LV} = 41.7$  for epoxy-polyamide adhesive. It also indicates that the untreated surface is that of polyethylene. (It is also clear that the surface tension of the adhesive arises essentially from dispersion forces:  $\gamma_{LV}^d \approx \gamma_{LV}$ .)

The increased adhesion due to successive treatments of polyethylene must therefore be due to changes in its surface. (On the rough assumption that  $b$  does not alter, a surface giving  $\theta = 19^\circ$  has  $\gamma_c \approx 40$  dyne/cm.) The most comparable case found involves the results of de Bruyne<sup>6</sup>. The failing stress of epoxy resin/polyethylene bonds increased with decrease in the contact angle of water on surfaces oxidized with chromic acid, a trend which Zisman<sup>5</sup> attributed to an increase in  $\gamma_c$ .

The considerations discussed help to give insight into factors involved in adhesion to plastics. It must, however, be mentioned that thermodynamic arguments give little direct information about the magnitude of shearing forces parallel to the surface required to break adhesive bonds, and that with polymers, part of the energy required to break an adhesive bond may be expended in causing deformation of the solid<sup>2</sup>.

## CHEMISTRY

## Band Width of the OH-stretching Vibration in Solid Alcohols

THERE have been many theories<sup>1</sup> advanced to explain the extremely broad OH-stretching vibration ( $\nu_{OH}$ ) in hydrogen bonded molecules. None of these theories fully explains the  $\nu_{OH}$  band width for all types of hydrogen bonded systems and many of the theories cannot be tested experimentally. We wish to report experimental evidence that the OH-stretching vibration in solid alcohols is not inherently broad, and that the breadth normally observed results from crystal interactions through nearest neighbour or first order coupling between OH groups along the hydrogen bond chain. Spectra of single crystals were obtained in a diamond window high pressure cell with techniques previously described<sup>2</sup>. Low temperature spectra were obtained in a conventional Dewar cell.

It has been well established<sup>3</sup> that intermolecular interactions associated with crystallinity can best be detected by isotopic dilution and mixed crystal studies. Fig. 1 shows such pertinent spectral data for various degrees of deuteration of solid *n*-decanol. With increasing dilution by *n*-decanol-OD, the  $\nu_{OH}$  sharp-broad doublet coalesces, and at high dilution becomes a singlet. At the same time,  $\nu_{OD}$  changes from a narrow singlet at low concentration to a sharp-broad doublet at high concentration analogous to the shape of  $\nu_{OH}$  in the pure OH compound. These deuteration studies leave no doubt that the appearance of two bands was caused by crystal splitting. Another equally important point is that the decoupled singlet OH band is quite narrow. In the lower spectrum of Fig. 1 we measured a half-band width of  $30\text{--}40\text{ cm}^{-1}$  even though the deuteration was not sufficient to decouple completely the OH vibration.

The sharp-broad character of the coupled doublet is seen more clearly in Fig. 2. This shows polarized spectra of single crystals of *n*-decanol at both low and high pressure. At low pressure, the bands are completely separated by polarization into a sharp band at  $3,410\text{ cm}^{-1}$  and a broad band near  $3,320\text{ cm}^{-1}$ . At high pressures, both  $\nu_{OH}$  components shift to lower frequencies, but the broad, lower frequency component shows a greater shift.

The explanation of these experimental observations can be seen with the aid of Fig. 3. Here we have assumed a

Fig. 1. Infra-red spectra of low temperature solids of deuterated *n*-decanol. OH/OD: 100/0, 85/15, 45/55, 25/75. \*Water.

planar hydrogen bonded chain of alcohol molecules (ROH) where the hydrocarbon portion (R) is considered as a point mass. In Fig. 3, the large circles represent R, dark circles represent oxygen atoms and the small, light circles represent hydrogen atoms. There are two vibrations due to the phase relationship of adjacent OH movements along the hydrogen bonded chain.

It is apparent from Fig. 3 that the in phase vibration would favour a tautomerization to the lower equivalent structure, whereas the opposite movement of the protons in the out of phase vibration would not favour such a tautomerization. It would be expected that such a tendency towards tautomerization would lead to a broadened absorption band for the in phase vibration, while the lack of tautomeric contribution in the out of phase vibration would lead to a more normal, narrow band. While compression because of increasing pressure would shorten the hydrogen bonds and lead to low frequency shifts for both components of  $\nu_{OH}$ , the pressure shift would be greater for the in phase vibration.

In addition, the resultant dipoles of these two vibrations would be very nearly at right angles to each other, thus

Fig. 2. Polarized infra-red spectra of a single crystal of *n*-decanol in diamond-window high-pressure cell. The upper curves are spectra (electric vector  $90^\circ$  apart) at low pressure. The lower curves are spectra (electric vector  $90^\circ$  apart) of the sample at high pressure.

Fig. 3. Coupled OH vibrations of hypothetical alcohol solid.

accounting for the experimentally observed polarization data.

We therefore conclude that experimentally observed splitting of  $\nu_{OH}$  in a solid alcohol arises from nearest neighbour or first order coupling of adjacent OH groups along the hydrogen bonded chain. This splitting alone leads to an increased band width for  $\nu_{OH}$ . In addition, coupling favours tautomeric forms which contribute to an increased band width for some components of the split OH vibration. Interaction with low frequency hydrogen bond modes ( $\nu_{OH} \dots O$ ) may also account for some of the breadth of  $\nu_{OH}$ . The coupling and tautomerism must be present, however, for this interaction to take place. Thus nearest neighbour coupling is the underlying reason for the breadth of  $\nu_{OH}$  in solid alcohols.

The decoupled OH-stretching vibration of a strongly hydrogen bonded solid alcohol gives a narrow singlet absorption with a half band width as low as  $30 \text{ cm}^{-1}$  and possibly even lower. Thus the OH vibration is not inherently broad. This narrow band shape may be general for many hydrogen bonded systems. This is now being investigated.

### Electronic States of Gaseous Fluorides of Scandium, Yttrium and Lanthanum

SOME of the more obvious features in the spectra of scandium fluoride ( $\text{ScF}$ )<sup>1,2</sup> and yttrium fluoride ( $\text{YF}$ )<sup>2,3</sup> have been described. The absorption and fluorescence spectra of  $\text{ScF}$  in low temperature matrices have now been observed<sup>4</sup>, and calculations<sup>5</sup> support the experimental finding that the ground state of  $\text{ScF}$  is  $^1\Sigma^+$ . Some analogies<sup>6</sup> may be drawn between the states of  $\text{ScF}$  and those of the isoelectronic molecule  $\text{TiO}$ . We have now carried out rotational analyses of a number of bands which have not been described before, and the purpose of this paper is to summarize the present position. For the most part the spectra have been observed in absorption in a carbon tube furnace at about  $2,000^\circ \text{C}$ , but some bands have also been photographed in thermal emission.

$\text{ScF}$  shows absorption systems based both on  $X^1\Sigma^+$  and on an excited  $^3\Delta$  state. No intercombination bands have yet been seen. Data on the singlet and triplet states are given in Tables 1 and 2.

A surprising feature of the state  $B^1\Pi$  in  $\text{ScF}$  is that the  $\Lambda$  doubling changes rapidly with  $v$ : in  $v=2$ ,  $q = -0.00046$ , and becomes  $-0.00105 \text{ cm}^{-1}$  in  $v=0$ . The doubling is in the sense requiring a  $^1\Sigma^-$  state lying below  $B^1\Pi$ . Such a state is hardly to be expected on any view of the likely low lying electron configurations in this molecule, and it

$\mu = 13.359 \text{ A.M.U. } r_0 (X^1\Sigma^+) = 1.791 \text{ \AA}$ .

\* These states all show perturbations.

$^\dagger q_0 = B_{11}^\dagger - B_{11} = -0.0020 \text{ cm}^{-1}$ .

$^\ddagger$  Values of  $q$  in this state may need revision upwards.  $q_0 = -0.00105$ ,  $q_1 = -0.00071$ ,  $q_2 = -0.00046 \text{ cm}^{-1}$ .

Table 2. TRIPLET STATES OF SCF

State	$T_{00}$	$\Delta G_{\frac{1}{2}}$	$x_c\omega_e$	$B_0$	$10^3 a$
$^3\Phi_1$	27,202.2 + $x_2$	—	—	0.3463	—
$^3\Phi_2$	27,171.1 + $x_2$	—	—	0.3441	—
$^3\Phi_3$	27,138.2 + $x_1$	—	—	0.3413	—
$(^3\Pi_2)$	18,361.4 + $x_2$	—	—	0.3677	—
$(^3\Pi_1)$	18,336.0 + $x_2$	—	—	—	—
$^3\Phi_4$	15,317.6 + $x_2$	—	—	0.3530	3.10
$^3\Phi_5$	15,277.5 + $x_2$	564.5	2.96	0.3511	—
$^3\Phi_6$	15,234.4 + $x_1$	—	—	0.3490	—
$^3A_1$	$x_3$	643.05	—	0.3693	2.58
$^3A_2$	$x_2$	642.92	3.03	0.3652	2.54
$^3A_1$	$x_1$	642.85	—	0.3610	2.50

The rotational constants given are effective, case  $a$  values: however, the energy levels do not entirely follow simple case  $a$  formulae. The constants given for  $^3\Pi_2$ — $^3A_1$  follow from an incomplete analysis of a system with closely spaced and perturbed rotational structure. At least three other systems with structure which seems to be too complex for singlet transitions have been observed.

may be rather that the perturbing state is the  $\Omega=0$ -component of a  $^3\Sigma^+$  state.

A strong O—O sequence exists at 21,927  $\text{cm}^{-1}$ , the structure of which suggests  $^3\Delta$ — $^3\Delta$  in which the coupling constants in the two states are almost equal. The bands are degraded  $V$ , and if the lower is still  $^3\Delta$ , then the upper state has  $\Delta G_{1/2} = 717.4$

$$x_c\omega_e = 3.64 \text{ cm}^{-1}$$

Secondly, there is a complex group at 26,300  $\text{cm}^{-1}$ , degraded  $R$ , and finally there are violet degraded bands with O—O head at 35,942.0  $\text{cm}^{-1}$ .

In YF, singlet systems dominate the absorption spectrum, and the one triplet system so far known, and assigned as  $^3\Phi$ — $^3\Delta$ , partly by analogy with ScF, appears rather weak in absorption. Thus the  $^3\Delta$ — $^1\Sigma^+$  separation may be a little bigger in YF than in ScF. Constants for YF are given in Tables 3 and 4.

Table 3. SINGLET STATES OF YF

$^3A_1$	$x_1$	576.4	2.39	—

$$r_0(^3A_2) = 1.94 \text{ \AA}.$$

The vibrational constants are from ref. 3.

A preliminary study of the absorption spectrum of LaF has revealed bands in the region 7650–8650  $\text{\AA}$ . The rotational analysis of two bands, red degraded, with single  $R$  and  $P$  branches, has been completed. Constants are given in Table 5. They are most probably the 1—O and O—O bands of a  $^1\Sigma^+$ — $^1\Sigma^+$  system. The lower state is probably the ground state of LaF, but a  $^3\Delta$  state may also be expected to give rise to absorption bands. Rotational structure may also be seen in red degraded bands at 13,059 and 13,029  $\text{cm}^{-1}$ : these bands seem to belong to a second infra-red system of LaF.

Table 5. STATES OF LaF

State	$T_{00}$	$\Delta G_{\frac{1}{2}}$	$B_0$	$10^3 a$
$^1\Sigma^+$	11,661.9	489.4	0.2273	1.1
$X^1\Sigma^+$	0	550*	0.2458	—

\* From Kratzer's relation.

$$\mu = 16.718 \text{ A.M.U.}, r_0 = 2.026 \text{ \AA}.$$

Violet degraded emission bands between 3200 and 3625  $\text{\AA}$  have also been ascribed<sup>7</sup> to LaF. They do not seem to

bear any relation to the bands described here, and some of the vibration frequencies derived, 682 and 657  $\text{cm}^{-1}$ , for example, which are larger than in the ground state of YF, seem to be too big for LaF.

## CYTOLOGY

### Antigen and Antibody Localization in Hassall's Corpuscles

HASSALL's corpuscles in the guinea-pig thymus take up carbon<sup>1,2</sup> and Evans blue<sup>3,4</sup> from the circulation. In man, these corpuscles contain gamma globulin<sup>5-7</sup>. We therefore studied the localization in the thymus of albumin and globulin injected into the circulation by autoradiography and compared it with that in other lymphoid tissues.

Twelve immature female guinea-pigs (Hartley strain), weighing 260–320 g, were grouped into pairs of similar weight. Potassium iodide (50 mg/l.) and sodium chloride (4.5 g/l.) were added to the drinking water from the day before the experiment began, in order to block iodide uptake by the thyroid. The thymus was locally X-irradiated and received a tissue dose of 300 r., as described before<sup>1</sup>. Six animals were irradiated—three were allowed to survive for 2 days and three for 8 days. The same number of paired control animals was used.

Within 1 h of irradiation, animals were injected by the intracardiac route with one of the following: human serum albumin (HSA) (Hoechst) (eight animals) or guinea-pig gamma<sub>2</sub> globulin (GGG) (four animals). The latter was highly purified and showed a single precipitin band on immunoelectrophoresis. Each protein was trace-labelled with iodine-125 (R.C.C., Amersham, IMS-3) by the method of McFarlane<sup>8</sup>. With HSA, specific activities of 6.6 and 4.4 mc./mg were obtained, and giving 4–6  $\mu\text{c./g}$  body-weight produced good autoradiographs. Four animals received the smaller dose and four others the larger. The latter group was given, in addition, one intraperitoneal injection of 3 mg rabbit anti-HSA antibody plus 5 mg of mepyramine maleate 1 or 2 days before being killed. The labelled GGG had a specific activity of 0.3 mc./mg. Four animals each received 4  $\mu\text{c./g}$  body-weight.

Animals that had not received antibody were anaesthetized, perfused with saline through an intracardiac cannula to remove labelled protein from the circulation, and immediately killed with ether. Tissues were fixed in 10 per cent formol saline and processed. Sections were cut (5–7  $\mu$ ) from two blocks: one contained the two lobes of the thymus and a cervical node, the other the spleen and a mesenteric node. Autoradiography on histological sections was carried out with Kodak 'AR 10' stripping film, exposed for 2–6 weeks, developed and stained with methylene blue.

Two days after injection, the label from both proteins was diffusely distributed over thymic lobules with accentuation over interlobular septa and blood vessels. The

Fig. 1. Autoradiograph of X-irradiated thymus from an animal that was injected with HSA- $^{125}\text{I}$  2 days before death and with rabbit anti-HSA antibody 1 day before death. There is selective accumulation of HSA in parts of Hassall's corpuscles. A "compound" corpuscle shows uptake of the protein at one end. Other corpuscles show variable amounts of labelling (exposure time for ARG 4 weeks, methylene blue,  $\times c. 30$ ).

Fig. 2. Another area from the same animal as Fig. 1, showing concentric lamellar pattern over one corpuscle, while others show heavy confluent aggregations of silver grains (exposure time for ARG 4 weeks, methylene blue,  $\times c. 30$ ).

greatest accumulation of protein, however, was seen in Hassall's corpuscles. Irradiation further enhanced the uptake by the corpuscles (Figs. 1 and 2) and many became hyperplastic. The appearance suggested active concentration. At this time, the proteins were not localized in germinal centres in spleen or lymph nodes, but were diffusely spread over the parenchyma of these organs with marked accentuation of vascular channels and lymphatic sinuses (Fig. 3).

After 8 days the concentration of proteins was of lesser intensity, but still uniformly distributed over thymic lobules, with the exception of the corpuscles which were still prominent (Fig. 4). The concentration in the spleen and lymph nodes was similar to that of the thymus. In two animals that had had antibody 2 days earlier, there was virtually no label over the capsule, interlobular septa or cortex of the thymus. Only a small amount was present in the medulla but there was intense circumscribed labelling that clearly delineated the corpuscles (Fig. 5). Proof that this was caused by antigen and not by released iodine was provided by the follicular pattern in spleen and lymph nodes (Fig. 6) as described by McDevitt *et al.*<sup>9</sup>.

The present investigation demonstrates the rapid entry of homologous and heterologous serum proteins into the thymus of the guinea-pig. The intensity of label over the gland is of the same order as that found over lymph nodes and spleen. This agrees with previous quantitative studies<sup>4</sup>. Furthermore, there is focal concentration in

Hassall's corpuscles independent of previous sensitization. Irradiation increases the size and number of corpuscles that are "active" in the uptake of proteins, only a few remaining "quiescent", similar to the behaviour found in the phagocytosis of carbon<sup>2</sup>. These observations conflict with studies of antigenic localization in the thymus after intravenous injection in the mouse and the rat<sup>10-12</sup>. In these animals, however, the thymus is devoid of Hassall's corpuscles.

The speed of localization of antigen in Hassall's corpuscles of the immature guinea-pig compares with that found in germinal centres of the spleen of unprimed chicks aged 4-7 weeks<sup>13</sup>. In the latter, antigen was found as early as 2 days after intravenous injection, long before antibody had formed locally. Comparing the Hassall's corpuscles of immature guinea-pigs and germinal centres of the chick spleen, it is seen that both readily take up

Fig. 3. Autoradiograph of a cervical lymph node from the same animal as in Fig. 1. The foreign protein is present in lymphatic channels around, but not inside, the germinal follicle (exposure time for ARG 4 weeks, methylene blue,  $\times 12$ ).

Fig. 4. Autoradiograph of thymus from a control animal that was injected with GGG- $^{125}\text{I}$  8 days before death. Heavy labelling is seen over a corpuscle which also shows an autoradiographic artefact. Such artefacts are not uncommon and have also been observed over other concentric structures such as aorta (personal communication from C. W. M. Adams). Labelling of lesser intensity is also seen in the adjacent medulla (exposure time for ARG 3 weeks, methylene blue,  $\times 120$ ).

Fig. 5

Fig. 6

Fig. 5. Autoradiograph of X-irradiated thymus from an animal injected with HSA-<sup>125</sup>I 8 days before death and rabbit anti-HSA antibody 2 days before death. Foreign protein is present in Hassall's corpuscles but of lesser intensity than seen 2 days after injection (exposure time for ARG 4 weeks, methylene blue,  $\times c. 30$ ).

Fig. 6. Autoradiograph of cervical lymph node from same animal as illustrated in Fig. 5. Concentration of antigen inside germinal follicles is clearly seen (exposure time for ARG 4 weeks, methylene blue,  $\times c. 30$ ).

circulating antigen in the unprimed state and both, at a later stage, contain gamma globulin. This may be relevant to the human foetal thymus where gamma globulin containing corpuscles are found in the eighth month of intrauterine life<sup>6</sup>.

The present investigation fails to support the concept of a barrier between blood and thymus<sup>11</sup>, at least with regard to serum proteins in the guinea-pig. If these findings are applicable to man, it suggests that a proportion of the gamma globulin found in human Hassall's corpuscles might come from the circulation and may not be elaborated locally.

These results have affirmed that Hassall's corpuscles in the guinea-pig thymus are by no means effete vestigial structures—on the contrary, they are sites of intense activity, showing phagocytosis, antigenic localization, uptake of gamma globulin and rapid changes in size caused by accretion of cells and cellular debris<sup>2</sup>. The rapid entry into the thymus of serum proteins of differing molecular sizes argues against a blood-thymus barrier in the guinea-pig.

I thank Dr J. H. Humphrey, National Institute for Medical Research, Mill Hill, for help and the rabbit anti-HSA antibody, Mr R. G. Q. Leslie of Guy's Hospital Medical School for the gamma<sub>2</sub> globulin, and Professor C. B. Allsopp, Miss J. R. A. Smith, Mr Ronald Morgan and Miss Lesley Kennedy

### Deletion of the Long Arm of Chromosome 16 and an Unexpected Duffy Blood Group Phenotype reveal a Possible Autosomal Linkage

CHROMOSOME deletions are ideal material for identifying gene loci, by the correlation of the absence of part of a chromosome with a particular phenotype. We have recently studied a child who demonstrates this cytogenetic principle. A 26 month old mildly retarded Caucasian female was found to be heterozygous for a deletion of the long arm of chromosome 16. Analysis of autosomal marker systems in the propositus and her family suggests that the location of the genes determining the Duffy blood system might be on the chromosome 16.

The propositus was a well developed, well nourished female who was below the third percentile in size. She had low set ears with flattening and over-rolling of the superior helix, epicanthic folds, widely spaced nipples, tapered fingers and a valgus deformity of the second toe crossing the third. There was notable dimpling over the shoulders,

Fig. 1. Karyotype from the propositus. Note the deleted long arm on the left hand chromosome of pair 16. (Lymphocyte culture.)

elbows, knees, knuckles, sacrum and the spinous processes of L-2 and L-3. Routine laboratory and X-ray studies were within normal limits, and her dermatoglyphics were not unusual. The child had secondary bilateral optic pallor. She also had hearing loss, with serviceable hearing in the right ear and profound loss in the left.

The propositus had forty-six chromosomes, with a single heteromorphic pair. One chromosome 16 was shorter than its normal homologue (Fig. 1). This abnormality was visible in every cell. A secondary constriction was frequently observed in the shorter arm of the anomalous chromosome 16, which we interpret as having a deletion (either interstitial or terminal) distal to the secondary constriction of the long arm of the normal chromosome 16.

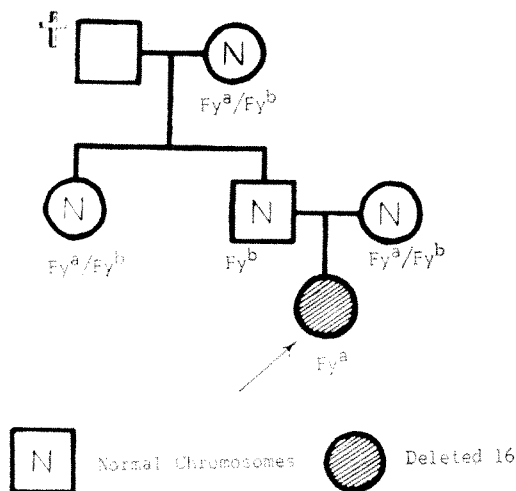

Fig. 2. Pedigree of the W. family. The Duffy blood group phenotypes are indicated.

Fifteen autosomal marker systems were investigated to see whether the loss of one or more was associated with loss of chromosomal material in the child. Heterozygosity allows us to state that the loci of the MNS and Rh red cell antigens are not on the deleted chromosome. Only the Duffy blood group gave unexpected results (the pedigree is given in Fig. 2). The propositus should be either  $Fy^bFy^b$  or  $Fy^aFy^b$ . Her  $Fy^a$  phenotype suggested that she was hemizygous for the locus. The father, however, could be heterozygous for  $Fy^b$  and the  $Fy$  allele for which the corresponding antibody has not been found. (The  $Fy$  gene, which has a frequency of 83–90 per cent in Negroes, is estimated to have a frequency as high as three per cent in Europeans<sup>1</sup>.) If that were the case the father of our propositus would be  $Fy^bFy$  and the propositus  $Fy^aFy$ . Dr Bruce Chown of the Rh laboratory, Winnipeg, Canada, kindly supplied an anti- $Fy^b$  serum (Sturg.) which when used neat also reacts with  $Fy$ . The cells of the mother and father reacted strongly with this serum, but the cells of the child were non-reactive. The Duffy phenotypes were checked with five anti- $Fy^a$  sera and five anti- $Fy^b$  sera (and all gave identical results). Dosage effects could not be obtained with these sera. The other blood group systems provide no evidence that this child is extramarital.

We therefore conclude that either the propositus has a previously undescribed  $Fy$  allele or that the absence of the expected  $Fy^b$  allele in the child is the result of the loss of chromosomal material which includes the locus of the Duffy gene.

We thank Dr Bruce Chown for the serum, anti- $Fy^b$  (Sturg.), and Dr Baruch Blumberg for analysing serum

proteins. This research was supported in part by grants from the US Public Health Service.

### Monolayer Cultures of Insect Cell Lines and their Inoculation with a Plant Virus

TWENTY-SEVEN years after Trager<sup>1</sup> reported short term survival and growth of silkworm cells from dissected female gonads, Grace successfully established continuous insect cell lines *in vitro* from ovarian tissues excised from diapausing pupae of *Antheraea eucalypti*<sup>2</sup>. The various attempts, during the interim, to improve *in vitro* growth of insect cells have been critically reviewed<sup>3-5</sup>.

Cultivation of leafhopper cells is of special interest, because it may provide, for those plant viruses that multiply in their vectors, a method of study which has long been available for researchers on phage and vertebrate viruses. Recently there have been successful attempts to obtain growth of cells of several leafhopper species by explanting tissues from certain nymphal or imaginal organs<sup>6,7</sup> or young embryos<sup>7-9</sup>. Plasma cultures derived from the ovary, hypodermis and digestive tract of a few cicadellids survived limited transplantations with evidence of mitosis<sup>6</sup>. Primary cultures in liquid media from embryonic tissues of *Macrosteles fascifrons*, *Dalbulus maidis*, *Agallia constricta*<sup>7</sup> and of *Nephotettix cincticeps*<sup>9</sup> could be maintained for several months. Mitsuhashi and Maramorosch<sup>7</sup> have reported that cells which formed extensive sheets surrounding tissue explants in the primary cultures grew very poorly when subcultured, despite their immediate attachment to glass surfaces. Such cells, separated from tissue explants, soon stopped growing and degenerated. Recently, primary tissue cultures of *Agallia constricta*, which transmit wound tumour virus (WTV), were inoculated with WTV and infection demonstrated by fluorescent antibody staining and infectivity tests<sup>10</sup>. There had been previous reports of the inoculation of leafhopper tissue cultures with aster yellows virus<sup>11</sup> and rice dwarf virus<sup>12</sup>; however, the evidences of infection seem inconclusive and the recovery of virus from inoculated cultures was either not attempted or was unsuccessful. Here we describe the establishment and maintenance of cell lines from *A. constricta*, the formation of monolayers by the cells and their inoculation with WTV.

To obtain primary coverslip cultures, young embryos of *A. constricta*, dissected from eggs laid 7 days previously in the petioles of crimson clover plants (*Trifolium incarnatum* L.), were explanted as described by Chiu *et al.*<sup>10</sup>. In order to attain a sufficient cell population per culture, 30 or 60 mm sealable Petri dishes were used. Usually, twenty or more pieces of embryonic tissue were placed in a small quantity of medium in the centre of each Petri dish and incubated at room temperature (about 24°C). Treatment of the pieces of embryo for 15 min in a 0.25 per cent trypsin solution before explanting improved initial growth of cells but was not essential. Initially, the medium developed by Mitsuhashi and Maramorosch<sup>7</sup> was found satisfactory for starting primary cultures, but later the growth medium described here was found to give equally good results and, indeed, for continuous culture was better.

Within a few hours after the cultures were started, attachment of dissociated cells and small groups of cells could be seen. These isolated cells and small groups, however, seldom survived long. Successful cultures were dependent on the attachment of the larger explanted tissue pieces to the glass. New cells began to appear from attached embryo fragments in 24–48 h. As these cells increased in number, cell sheets began to form, to expand gradually and eventually to engulf the original tissue explants. Such cultures could be maintained for several months by changes of medium at weekly intervals. The cell types that have been described in primary cultures of *Macrosteles fascifrons*<sup>7,13</sup> were also observed in those of *A. constricta*.

Early attempts to subculture the cells with the medium of Mitsuhashi and Maramorosch failed. Successful subculturing was obtained later with a medium based on Schneider's salt solution<sup>14</sup> at half strength. Each 100 ml. of our medium contained 400 mg *D*-glucose, 105 mg sodium chloride, 80 mg potassium chloride, 185 mg  $MgSO_4 \cdot 7H_2O$ , 30 mg calcium chloride, 30 mg potassium dihydrogen phosphate, 35 mg sodium bicarbonate, 650 mg lactalbumin hydrolysate, 500 mg 'Yeastolate', 17.5–20 ml. foetal bovine serum, 10,000 U penicillin, 10,000 µg streptomycin, 5,000 µg 'Neomycin', 250 µg 'Fungizone'. The inorganic salts can be prepared in two solutions: (a) a solution of all salts, except sodium bicarbonate, at five times the final concentration (sterilized by filtration) and (b) a solution of sodium bicarbonate at ten times the final concentration (sterilized by autoclaving). Stock solutions of glucose (4 g/100 ml.), lactalbumin hydrolysate (3.25 g/100 ml.) and 'Yeastolate' (5 g/100 ml.) can be sterilized by filtration. The foetal bovine serum is heated at 56° C for 30 min shortly before its incorporation in the medium. In preparing the medium, one must be careful to avoid concentrations of any of the ingredients which will cause irreversible precipitations. To make 100 ml. of the medium the various stock solutions of components may be added to 20 ml. of water in the order given. Antibiotics in stock solutions can be added just before supplying water to make a final volume of 100 ml. The medium has a pH of about 7.0 without adjustment.

Cell growth was less satisfactory in early subcultures without the substitution of 2.5 ml. of insect or lobster haemolymph for a like quantity of foetal bovine serum. (Haemolymphs were also heated at 56° C for 30 min before incorporation.) This medium supported vigorous

cell growth after cell dispersion after trypsinization. In one case medium that contained 20 per cent foetal bovine serum but no insect or lobster haemolymph yielded a cell line from *A. constricta*. Once adapted, the cultures grew continuously and well without insect or lobster haemolymph.

Nine cell lines of *A. constricta* have been passed through 7–55 subcultures made at intervals of 4–8 days. Details will be given here for the establishment of only one of these cell lines, namely, AC2 (an abbreviation for *Agallia constricta* cell line 2) which has been subcultured more than fifty-five times. On December 16, 1965, the primary AC2 culture was started by explanting embryonic tissues into a 60 mm sealable Petri dish. This culture was maintained in Mitsuhashi and Maramorosch's medium until early March when a decreasing rate of cell growth and darkening of the explanted tissues became apparent. On March 7, 1966, after the medium had been removed, the culture was exposed for 10 min to 0.05 per cent trypsin in Rinaldini salt solution free of calcium and magnesium ions. Trypsinization was stopped by the addition of an equal volume of growth medium containing foetal bovine serum (17.5 per cent) and haemolymph of *Antheraea eucalypti* (2.5 per cent). Gentle pipetting at this stage aided cell dispersion. After at least 6 h, when most of the living cells had become attached to the glass surface, the medium was changed and the floating dead cells together with some tissue pieces were removed. Subculturing by the same procedure was later repeated four times at 7–8 day intervals with the Petri dish unchanged but with the medium wetting greater areas each time. The brief trypsinization adopted did not suffice to disperse the cells completely and this proved to be advantageous because better growth was noticed at this stage from cells in clumps or from pieces of tissue.

Beginning on April 4, 1966, subculturing was carried out regularly by a procedure which involved trypsinization for 6–8 min in 0.05 per cent trypsin to dissociate the cells, centrifugation for 2 min at 200*g* and dispersion of the sedimented cells in medium for distribution to suitable containers. With a seeding density of  $4.8 \times 10^6$  cells in 4 ml., confluent monolayers were obtained in 3 days at 27° C in disposable plastic bottles with a useful flat surface of 25 cm<sup>2</sup>. In a 50 mm disposable plastic Petri dish 3 ml. of such inoculum was adequate and growth was obtained without adjustment of the supply of carbon dioxide. It should be noted that the period between starting the primary culture and the first subculturing was unnecessarily long in this case. Later experience indicated that successful subculturing could be achieved when extensive cell growth was attained about 3–4 weeks after starting primary cultures and established cell lines could be attained in another month.

All nine cell lines of *A. constricta* were comprised predominantly of epithelial types of cells (Fig. 1), although some variations in cell morphology and growth habit were noted among the lines. One cell line of *A. constricta* had distinctly more slender cells than did other lines. Although a steady growth rate was reached, none of the nine cell lines attained uniformity in cell morphology. Giant cells were intermingled with the predominant epithelial cells. Groups of cells with distinctive features emerged here and there when subculturing was infrequent. We made no attempt to determine whether these various cell types contained the symbionts which occur in leafhoppers and which may be retained in cultured cells derived from them<sup>7</sup>.

All the established *A. constricta* cell lines were susceptible to WTV prepared either

Fig. 1. A portion of a monolayer culture of *Agallia constricta* cells grown in a disposable Petri dish for 72 h.

Fig. 2. Cells of *A. constricta* stained with fluorescent antibody 48 h after inoculation with WTV. Non-infected cells which did not fluoresce are not clearly seen in the picture. Inset: Cell of *A. constricta* stained with fluorescent antibody 18 h after inoculation. Note the perinuclear location of WTV antigens.

from infected insects or from root tumour tissue of clover plants as previously described<sup>10</sup>. By the direct method of fluorescent antibody staining, virus antigen could be detected 12 h after inoculation and incubation at 30° C. Later, infected cells fluoresced more intensely and discrete stained spots appeared in the cytoplasm (Fig. 2), frequently in perinuclear locations (Fig. 2, inset). Infected lines, with 75 per cent or more of the cells positively stained, showed a growth rate comparable with the healthy lines. This became obvious when cultures inoculated with WTV were compared with healthy cultures of the same cell line, AC2, for ten consecutive subcultures. Seeding density ( $N_0$ ) was adjusted to  $1 \times 10^6$  cells per ml. or to a close approximation of this concentration. After the cells had attached at room temperature, cultures were placed in an incubator at 27° C. Cell counts were made for two 30 ml. bottles the next day ( $N_1$ ) and again for two bottles 4 days after subculturing ( $N_4$ ). There was no significant difference between the healthy and infected cultures in the ratios of  $N_4/N_1$  which were  $1.817 \pm 0.233$  for the healthy and  $1.765 \pm 0.101$  for the infected, respectively. The  $t$  test revealed a significantly lower ratio of  $N_1/N_0$  for the inoculated culture and this seems to indicate less satisfactory attachment of the infected cells during subculturing.

The method of establishing *A. constricta* cell lines and the use of our growth medium are applicable to other leafhopper species. We have succeeded in establishing two cell lines of *Agallia quadripunctata*, now at the ninth and twentieth passages. Cultures of *Aceratagallia sanguinolenta* and *Agalliopsis novella* are in early stages of subculturing.

We thank Drs T. D. C. Grace and Joan White for supplying us with haemolymph prepared by Dr Grace from *Antheraea eucalypti*.

### Ion Transport and Phosphorylation in Dried and Rehydrated Yeast Cells

BAKER's yeast, consisting of almost 70 per cent water, can be dried to a moisture content of 7–8 per cent of dry weight without serious impairment of viability or fermenting capacity<sup>1,2</sup>. The cell membrane in such cells seems to be altered in such a way that considerable leakage of cytoplasmic material occurs when the cells are suspended in water at or below room temperature. Suspension of the cells in water at 35°–45° C prevents excessive loss of cytoplasmic constituents<sup>3</sup>. The "active dry yeast" to be considered here is dried yeast rehydrated at 35° C in which the cellular permeability barrier has been restored. The lipid composition of yeast cells can be altered by

this process<sup>4</sup>. I have investigated the question of whether such cells are still capable of active ion transport, which is one of the normal membrane functions<sup>5–7</sup>.

Baker's yeast was washed by repeated centrifugation and resuspension, and brought to a "starved" condition by bubbling air through a 15 per cent suspension overnight. Packed cells were suspended in distilled water to give a 60 per cent suspension (0.6 g of fresh yeast/ml.).

To prepare dried yeast the packed cells were spread as a 1–2 mm layer on filter paper and dried in a thermostated box by circulating air at 35° C for about 3 h, until the moisture content was 7 per cent. On a dry weight basis 3 g of fresh yeast corresponds to 9 g of dry yeast. Resuspension of the dry yeast was effected at 35° C; subsequent fermentation experiments were carried out at 30° C. The course of transport of hydrogen ions to the medium, on the addition of glucose, was measured at constant pH by means of a Radiometer titrator-titrigraph, using *tris* (hydroxymethyl) aminomethane as the titrant. At intervals during fermentation 0.5 ml. of yeast suspension was pipetted into 4 ml. of ice-cooled 10 per cent trichloroacetic acid. The supernatant obtained after centrifuging the trichloroacetic acid suspensions was buffered with 15 ml. of 0.2 molar sodium acetate. Orthophosphate, in the presence of labile phosphates, was determined according to Lowry and Lopez<sup>8</sup> and Peel *et al.*<sup>9</sup>. Adenosine triphosphate was determined in the same solution by an enzyme method, using phosphoglycerate kinase and glyceraldehyde-3-phosphate dehydrogenase (Boehringer). In separate experiments, the time course of formation of inorganic polyphosphates was determined by a method developed by Lohmann and Langen<sup>10</sup> and modified by van Steveninck<sup>11</sup>.

Figs. 1 and 2 illustrate the differences in hydrogen ion production between normal, and dried and rehydrated, cells in comparable conditions. The stimulation of transport of hydrogen ions by potassium ions for normal cells is manifest in a considerable upward shift of the line giving total hydrogen ion production ( $\Delta H^+$ ) as a function of pH. No potassium-stimulation of hydrogen ion transport occurs in dried and rehydrated cells, and there is no uptake of potassium ions. There is still transport of hydrogen ions, but the slope of the line giving  $\Delta H^+$  as a function of pH is different. For the whole range of pH investigated production of carbon dioxide was virtually constant for both kinds of yeast.

Fig. 1. Normal yeast. Acid production as a function of pH; 0.5 ml. of 30 per cent glucose was added to 15 ml. of 60 per cent yeast suspension plus 3 ml. of water (a). (b) Water (1 ml.) plus 2 ml. of 1 molar potassium chloride was added before glucose addition ( $N_2$ , 30° C).

On the supposition that ion transport depends on a metabolic energy supply, factors influencing ion transport should have an effect on energy production and/or utilization. In this connexion the course of phosphate incorporation during fermentation is of some interest.

Time curves were obtained for intracellular orthophosphate ( $P_i$ ) during fermentation. The decrease in  $P_i$  immediately after glucose has been added to the yeast suspension is normally divided into two distinct phases. The initial fall in  $P_i$  was found to be virtually independent of the glucose quantity; at its end steady state concentrations of various phosphorylated intermediates of fermentation and of adenosine triphosphate are reached. The secondary decrease in  $P_i$  increases when larger quantities of glucose are added. As Fig. 3 shows, a constant concen-

Fig. 2. Dried and rehydrated yeast. Acid production as a function of pH: 0.5 ml. of 30 per cent glucose was added to a suspension of 3 g of dried yeast in 15 ml. of water (a). (b) The suspension was made in 13 ml. of water and 2 ml. of molar potassium chloride was added before glucose addition. ( $N_2$ , 30° C.)

Fig. 3. Normal yeast. Changes in orthophosphate ( $P_i$ ), inorganic polyphosphate (poly-P), and ATP during fermentation; 30 ml. of 60 per cent yeast; at  $t = 0.2$  ml. 30 per cent glucose was added.

Fig. 4. Comparison of normal yeast, azide-poisoned yeast and dried and rehydrated yeast. Orthophosphate ( $P_i$ ) time curves during anaerobic fermentation in conditions corresponding to those in Fig. 3. (a) Normal yeast; (b) normal yeast, with 1 mmolar  $NaN_3$ ; (c) dried and rehydrated yeast.

tration of ATP in this phase is maintained until all the glucose added is used up; then there is a return to a relatively low concentration of ATP. While ATP remains constant there is a steady rise in inorganic polyphosphate. Hydrogen ion transport occurs chiefly in the period between 5 and 8 min after glucose addition, that is the period of the secondary fall in  $P_i$  (ref. 7). Inhibitors of potassium-stimulated hydrogen ion transport, such as azide and 2,4-dinitrophenol, eliminate the secondary fall in  $P_i$  (Fig. 4).

Experiments with dried and rehydrated yeast cells gave  $P_i$  curves which were shifted upward when compared with the  $P_i$  curves for normal yeast, and resembling the  $P_i$  curves for yeast poisoned with azide.

Theoretically for each mole of glucose fermented 2 moles ATP can be produced. The actual rise in the concentration of ATP corresponds, however, to only a small fraction of the theoretical quantity. Apart from dissipation of energy as heat,  $\sim P$  appears to be utilized in a number of processes as outlined below:

In the presence of azide and similar inhibitors the time curve for ATP remains virtually unchanged. The high-energy intermediate indicated as  $\sim P$  compound  $X$  may become unstable; uncoupling of ion transport and polyphosphate formation from fermentation would be the result. In dried and rehydrated cells as well as in cells poisoned by azide, polyphosphate formation is in fact eliminated (my unpublished results).

Dehydration influences a number of processes requiring an intact membrane structure, "Active dry yeast" has an impermeable cell membrane, and hydrogen ion transport during fermentation is still possible. On the other hand, potassium ions do not enhance hydrogen ion transport, and are no longer taken up in an exchange between potassium and hydrogen. Inorganic polyphosphates, an important fraction of which has been localized at the cell membrane<sup>10,12,13</sup>, are no longer synthesized during

fermentation. Both with regard to an altered phosphorus metabolism and with regard to an impaired exchange between potassium and hydrogen "active dry yeast" resembles azide- or dinitrophenol-poisoned yeast.

## GENETICS

### Fundamental Theorem of Natural Selection

EDWARDS<sup>1</sup> has recently criticized Li's description<sup>2</sup> of his formula for the rate of change of mean fitness in a population as the "fundamental theorem of natural selection" on the grounds that Fisher's derivation<sup>3</sup> of the fundamental theorem used overlapping generations, whereas Li uses separate generations. Because Fisher<sup>3</sup> said that his theorem held "the supreme position among the biological sciences", and because at one time he worked on one of the many organisms which in the wild have non-overlapping generations<sup>4</sup>, it seems very unlikely that he thought the generation-system had any essential effect on his theorem, and it is not possible to exclude from consideration formulations with non-overlapping generations when discussing the generality of the theorem. True or untrue statements with one system of generations are likely to be just so with the other.

Although Fisher spoke of the "rigour of the demonstration"<sup>5</sup> of his theorem, its presentation is so opaque, even to mathematicians<sup>6</sup>, that it is hard to be sure it is rigorous; in view of the cases in which the theorem is not strictly true, it is better regarded as a brilliant creative approximation than a rigorous piece of mathematics. Thus Fisher thought it was true with or without dominance, with any number of loci and with any system of mating; in fact it is absolutely true only for a single locus without dominance under random mating<sup>2</sup>. When there is dominance the change in fitness lies between  $\frac{1}{2}$  and  $n$  times Fisher's value, where  $n < \infty$ . I shall discuss elsewhere some aspects of dominance and multiple loci<sup>6,7</sup>; there is no recent treatment of non-random mating, and it is instructive to consider the simplest case—inbreeding. Following Kimura<sup>8</sup>, the rate of change of mean fitness,  $\bar{M}$ , with time,  $t$ , is given, for two alleles, by

$$d\bar{M}/dt = 2q_0q_1(M_0 - M_1) \left( \frac{1}{2} d\bar{M}/dq_0 \right) \quad (1)$$

where  $q_0, q_1$  are the gene frequencies and  $M_0, M_1$  are the average fitnesses of the genes, and we ignore the effects of dominance.  $(M_0 - M_1)$  is Fisher's "average excess" ( $\alpha$ ) and if  $\frac{1}{2}(d\bar{M}/dq_0)$  were Fisher's "average effect" ( $\alpha$ ), then (1) would be identical with Fisher's  $2q_0q_1\alpha\alpha$ , which he called the genetic variance in fitness and which is always positive. But the quantity in (1) is not necessarily positive. Thus at a non-trivial equilibrium the rate of change of gene frequency

$$dq_0/dt = q_0q_1(M_0 - M_1) \quad (2)$$

is zero, and so also is the quantity<sup>9,10</sup>

$$d(\bar{M} + F\bar{M}_I)/dq_0 \quad (3)$$

where  $F$  is the inbreeding coefficient and  $\bar{M}_I$  the mean fitness of the inbred portion of the population. With inbreeding therefore  $(d\bar{M}/dq_0)$  is not zero at a non-trivial equilibrium. Now if the equilibrium is stable, (2) will be positive for gene frequencies lower than equilibrium and negative for higher gene frequencies. Because  $(d\bar{M}/dq_0)$  is likewise positive below and negative above its zero point, and because this zero point does not coincide with the equilibrium, it follows that in the region between these points one of the quantities  $(M_0 - M_1)$  and  $\frac{1}{2}(d\bar{M}/dq_0)$  is positive, the other negative. Thus equation (1) is negative and the change in fitness is not equal to Fisher's positive quantity  $(2q_0q_1\alpha\alpha)$ . The same applies to an unstable equilibrium. With random mating  $(M_0 - M_1) = \frac{1}{2}(d\bar{M}/dq_0)$  and (1) is the same as Fisher's expression. Inclusion of dominance adds a small correction analogous to that under random mating<sup>2</sup>, but does not alter the conclusions.

These manipulations can be made also for non-overlapping generations; as Edwards<sup>1</sup> and Li<sup>2</sup> say, Fisher's theorem seems to be at best approximate under general conditions.

### Caffeine-induced Mutagenesis in *Drosophila*

ANDREW<sup>1</sup> reported that caffeine is mutagenic for the *Drosophila* male when administered either by a larval feeding or by an adult injection method. Yanders and Seaton<sup>2</sup> later repeated these experiments, and found no indication of a mutagenic effect for caffeine by either method of administration. As far as the present communication is concerned, the interest of these reports lies in the conflicting results of the larval feeding treatments.

Andrew's larval feeding treatment<sup>1</sup> was carried out with a medium composed of treacle, semolina and agar (not seeded with yeast) to which 0.25 per cent caffeine was added, whereas Yanders and Seaton's medium<sup>2</sup> containing 0.25 per cent caffeine was composed of sucrose, dextrose and brewers yeast. In view of the observation by Novick and Szilard<sup>3</sup> of an antimutagenic effect of certain natural purine ribonucleosides (adenosine, guanosine and inosine) on the mutagenic effect of certain *N*-methylxanthines (including caffeine) on *Escherichia coli* cells grown in continuous (chemostat) culture, it seems feasible that the higher concentration of RNA and nucleotides (from the yeast) in Yanders and Seaton's medium might be masking the mutagenic effect of caffeine observed by Andrew on his medium. On the basis of this consideration, we have repeated the feeding treatment of *Drosophila* (Oregon-K) larvae with caffeine on a chemically defined and axenic medium from which all purine and pyrimidine sources may be omitted<sup>4</sup>. The experiments have been designed to test for a mutagenic effect of caffeine in the absence and in the presence of exogenous purine and pyrimidine sources (as supplied by yeast RNA): the toxic concentration of caffeine on the chemically defined medium is lower than on the usual *Drosophila* media, particularly in the absence of RNA.

The treatment medium was prepared by adding a Seitz-filtered solution of caffeine to the autoclaved chemically defined medium at 60° C. The medium was then dispensed as 25 ml. portions into small Petri dishes, and one hundred newly hatched axenic<sup>4</sup> larvae were added to each culture. The larvae were treated for 48 and 72 h with medium containing 0.05 per cent caffeine, and for 48, 96 and 240 h with medium with 0.075 per cent caffeine, after which they were transferred to a corresponding medium without caffeine to complete their development.

On emergence, males were individually mated to two Muller-5 females for 3 days for the detection of  $F_1$  complete sex-linked recessive lethal mutations, and one (or more) non-lethal  $F_2$  culture arising from each treated male was sampled for evidence of  $F_1$  sex-linked recessive lethal-mosaicism. This latter procedure detects those lethals which are not completely established throughout the gonad of the  $F_1$  female (and not detected as  $F_1$  complete lethals), but are lethal mutations which occur after a delay and are established in only a fraction of the gonad of the  $F_1$  female ( $F_1$  lethal-mosaic)<sup>5</sup>.

Tables 1 and 2 illustrate the results obtained for sex-linked recessive lethal mutations after larval feeding treatments at two concentrations of caffeine (0.05 and 0.075 per cent) in the chemically defined and axenic medium. There is no indication that caffeine increases the frequencies of  $F_1$  complete or  $F_1$  mosaic sex-linked recessive lethal mutations either in the absence or in the presence of RNA (0.3 or 0.6 per cent). These experiments thus lend no support to the observation by Andrew<sup>1</sup> that caffeine is mutagenic for the *Drosophila* male larva.

## Chromosome Marker Studies in the Irradiated Chick Embryo

THE repopulation of the irradiated adult animal by injected myeloid cells has provided a considerable amount of qualitative and quantitative data on haemopoietic stem cells<sup>1</sup>. The work reported here was designed to investigate the capacity of cells of various embryonic organs to populate the haemopoietic tissues of the irradiated embryo. The chick embryo is especially suited to such a study, first because haemopoietic cells can be injected intravenously into it, and second because the sex chromosome difference between male (ZZ) and female (ZW) cells provides a marker method for distinguishing the contributions of host and donor to haemopoietic recovery.

We have confirmed the acute mortality which has been reported<sup>2</sup> in chick embryos after irradiation, and this limits the total amount of radiation to which embryos can be subjected. After preliminary experiments, using various dosages of radiation, a total of 800 rads (dose rate 66 rads/min from a cobalt-60 source) was administered as a standard procedure to embryos which had been incubated for 13 days. In the strain of bird used (Rhode Island and White Leghorn) there was an acute mortality of about 20 per cent and about 75 per cent of remaining embryos hatched out. Some of the irradiated embryos were injected after incubation for 14 days with cell suspensions prepared from either 7 day yolk sac, 14 day spleen, 16 or 18 day bone marrow, or 14 or 18 day thymus. A total of  $10 \times 10^6$  cells of male sex (ZZ) were injected intravenously in each case. In an additional experiment, quantities of 0.1 ml. of whole blood removed from 13 day male embryos were injected into irradiated hosts.

After various intervals, but usually at 2 days after hatching, chicks which had been irradiated and injected with cells were treated with 'Colcemid' (Ciba) and killed 2 h later. If they were female (ZW), chromosome spreads were prepared from thymus, bursa of Fabricius, spleen, and bone marrow by a technique described previously<sup>3</sup>. These organs, removed from both injected and non-injected birds, were also examined histologically.

The results of the chromosome analysis are presented in Table 1. In the very short time period studied, there was a partial recolonization of haemopoietic tissues by yolk sac, spleen, bone marrow or blood cells. With the exception of one embryo which showed a low level of bursal chimerism, however, no comparable repopulation was found after injections of thymocytes.

Although haemopoietic recovery was incomplete in the thymus, bursa of Fabricius and spleen at the times of chromosome analysis, the results presented here do allow some tentative conclusions to be made about the potentialities of embryonic stem cells for haemopoietic development. After 7 days of incubation, the yolk sac is the only important site of haemopoiesis in the embryo and its activity is mainly directed towards the production of erythrocytes. Yolk sac cells from this stage, however, are

capable of populating both myeloid and lymphoid organs (thymus and bursa) in the irradiated embryo, which suggests that there are cells in the yolk sac which are pluripotential. Alternatively it might be suggested that there are within the organ distinct categories of stem cell already committed to particular types of haemopoietic differentiation. This seems less likely because the 7 day stage precedes both marrow and spleen haemopoiesis as well as bursal and thymic lymphopoiesis.

Although the yolk sac is the most likely primary source of stem cells with a range of developmental capacities, the results suggest that at later stages spleen, bone marrow and blood also contain these stem cells. Thus spleen cells which were mainly granuloid at the time of injection can populate both myeloid and lymphoid tissues. Cells which enter the thymus, however, lose their potentiality for alternative types of differentiation.

These results agree with other experimental data on embryonic haemopoiesis collected in this laboratory, which have shown that the development of the thymus<sup>1</sup>, bursa of Fabricius<sup>2</sup>, and spleen and bone marrow<sup>3</sup> are all dependent on the inflow of blood-borne stem cells. The cell type common to all these organs during the initial stages of haemopoiesis and present in the circulation throughout embryogenesis is a large basophilic cell with prominent nucleolus and irregular outline. Autoradiography suggests this cell is most likely to be the blood-borne stem cell (our unpublished results). If, as the present experiments suggest, the blood-borne stem cell is initially uncommitted, then its later differentiation into distinct cell types may depend on an inductive influence exerted by the organ anlage (epithelial in the thymus and bursa, mesenchymal in the spleen and marrow) into which it migrates.

In conclusion, the population of haemopoietic organs of the irradiated embryo by injected myeloid cells supports the role of blood-borne cells in embryo haemopoiesis and suggests that the embryo stem cell has a wide range of developmental capacities.

## MICROBIOLOGY

### Thermophilic Bacterium isolated on *n*-Tetradecane

GROWTH at the expense of hydrocarbons occurs in a wide variety of micro-organisms; Fuhs<sup>1</sup> listed more than 100 yeasts, bacteria and fungi with this characteristic. Scant information is available concerning the influence of temperature on microbial hydrocarbon oxidation. Four strains of micrococci have been checked for their ability to grow at the expense of octane, nonane and decane at 20° and 25° C (ref. 2). At the lower temperature there was good utilization of decane but none of the strains grew on this hydrocarbon at 25° C. Possibly such differences in growth response are related to an increase in vapour pressure of the *n*-alkane with an increase in temperature. According to Allen<sup>3</sup>, most if not all of the most important types of metabolism carried on by mesophilic bacteria can also be found among thermophilic bacteria. A variety of carbon sources can be utilized by thermophilic bacteria<sup>4</sup>, and some years ago a general survey of thermophilic bacteria was made using enrichment culturing<sup>5</sup>. No bacterium was selected from soil, fresh water or marine mud, or dry plant material when paraffin served as the carbon source. Presumably the paraffin was a mixture of long-chain saturated hydrocarbons.

A sample of mud from an oil-covered inlet of Lake McBride near Iowa City was inoculated into a basal salts medium<sup>6</sup> amended with 2 per cent *n*-tetradecane. After transfers in liquid media a pure culture was obtained by streaking an inoculum from the liquid enrichment medium on basal salts-agar plates to which hydrocarbon was added to filter paper placed in the cover of an inverted Petri dish. All incubations were at 60° C.

The organism obtained was a Gram-positive bacillus, 2.8 to 4.2  $\mu$  long by 0.5 to 0.7  $\mu$  wide, bearing terminal spores. Growth occurred in a temperature range of 45°–70° C, with optimum growth between 55° and 60° C. At the optimal temperature range good growth was observed in 24 h on basal salts-agar slants to which a layer of hydrocarbon was added to the base of the slant. On transfer to liquid medium containing hydrocarbon, visible growth was not seen until after 96 h, which seemed to indicate that a stimulatory growth factor was present in the agar.

Commercially available agars and agar subjected to various extraction procedures were used in growth experiments to ascertain if a stimulatory factor was present. The effect of these agars on growth was measured at 60° C in a basal salts medium to which 1.5 per cent of the various agar preparations was added. *n*-Tetradecane was

Table 1. GROWTH RESPONSE OF A THERMOPHILIC BACTERIUM TO *n*-TETRADECANE ON BASAL SALTS MEDIUM PLUS VARIOUS PREPARATIONS OF AGAR

Solidifying agent	Growth		
	24 h	48 h	72 h

0, No growth; 1, slight growth; 3, abundant growth.

added to the base of each agar slant. Results are shown in Table 1. Preparation No. 5 was dialysed against deionized water for 7 days and a portion of this was dried and extracted with methanol-chloroform for 7 days (No. 6). The washing procedure outlined by Dworkin and Foster<sup>6</sup> was followed for preparation 7. Thiamine and biotin are apparently removed by the extraction procedure used for No. 9 (ref. 7). Agar was replaced by silica gel as a solidifying agent in No. 10 (ref. 8). Only the purification procedure used by the manufacturer of "special-purified agar" appeared effective for the removal of growth stimulatory factor or factors from agar. It appears that growth of this thermophilic bacterium on *n*-tetradecane is unique in that it occurs without the addition of organic growth factors. Growth is obtained on a solid medium of silica gel and basal salts and in a liquid medium of basal salts with *n*-tetradecane as the only source of carbon in both cases.

The factor of aeration was considered in attempts to shorten the lag period because at 60° C the solubility of oxygen in water is decreased. When humidified air was sparged through the medium containing hydrocarbon there was no growth. Incubation in a gyrotory water-bath shaker (200 r.p.m.) at 60° C also inhibited growth. In similar conditions in a more complex medium—meat infusion broth—growth was observed within 24 h.

## Biochemical Balance and Synchronized Cell Cultures

In cell biochemistry, it is desirable to have criteria for identifying abnormal changes resulting from experimental manipulation, especially during the induction of synchrony. For this purpose, use has been made of the concept of unbalanced growth, first introduced by Cohen and Barner<sup>1</sup>, to explain the death of a thymine-requiring mutant of *Escherichia coli* as a result of continued cytoplasmic synthesis in the absence of proportional DNA synthesis. Most people who use this concept are doubtless aware that its foundation must be in the biochemical processes within individual cells and that the fundamental definition of "balance" should be at the cellular level. There are, however, examples in the literature in which it is concluded, on the basis of changes in the gross composition of mammalian cell cultures in which the age distribution of cells is changing, that growth is "unbalanced" without proper consideration of the possibility that the changes might

result merely from redistribution of individual cells in the several phases of the life cycle, rather than from significant changes in their composition.

These conclusions are based on the Campbell definition<sup>2</sup> that "growth is balanced over a time interval if, during the interval, every 'extensive' property of the system increases by the same factor". For large populations with an invariant distribution of ages, this formulates the results expected for a particular type of macro-system. As Zeuthen<sup>3</sup> points out, however, such a definition automatically categorizes all synchronous cell cultures as unbalanced because of periodic variations in their properties, although individual cells of the culture may be normal at all times. Similarly, it is impossible for a single mammalian cell to display a "balanced" growth pattern by Campbell's definition, although the individual cells determine the properties of the culture. This paradox results from the fact that the gross constancy of large populations results from the combination of two distinct requirements: (a) the periodic biochemical pattern of individual cells as they traverse the life cycle must be time-invariant (at least as averaged over an adequate number of cells and/or cycles); and (b) the fraction of cells in each of the several phases of the life cycle must be time-invariant. Clearly, the first requirement is fundamental to the concept and mechanism of balanced growth, but the second is, in this connexion, superficial and relates only to demographic properties of the culture.

We propose, therefore, that balanced states be defined in terms of the properties of individual cells and that the culture as a whole be classified on the basis of summation over the biochemical states of its members. For a single cell, an unbalanced state is one in which it has a composition not shown by any cell in the course of the "normal" life cycle. To the extent that all cells follow an identical sequence of development, each state corresponds to and succinctly defines a single "age" in the life cycle. Because of random fluctuations (for example, in generation time, in mass at birth and division), it is clear that a simple one to one correspondence between age and state does not exist. Rather, there are many possible alternative states between birth and division, and a given cell will traverse only a limited number of these states in the course of its life cycle. The totality of accessible states, however, can be identified in principle and the probability of alternates determined. Unbalanced growth then is growth which leads the cell into a state of abnormal composition.

For a culture of many cells, the state of the culture is determined by the distribution of the states of its component cells and is specified by enumerating the number of cells which are in each cellular state. The "balance" of a synchronous culture will depend not on the numerical distribution of cells among the available cell states but, rather, on whether or not some cells are in states not attained by any cell in the original random culture.

A multiplicity of balanced growth patterns must be allowed with any pattern capable of unlimited cyclic repetition regarded as balanced. Schaechter, Maaløe and Kjeldgaard<sup>4,5</sup> have demonstrated such a multiplicity in the adaptation of *Salmonella* to varying conditions of, for example, temperature, nutrition and cell concentration with concurrent changes in cell composition and growth patterns.

An example of the magnitude of effects which can result from a redistribution of cells in the life cycle is the experiment of Kim *et al.*<sup>6</sup> in which HeLa cells were treated with excess thymidine, which stopped DNA but not RNA and protein synthesis. An increase in total RNA by a factor of 1.36 was observed in the 11 h after cessation of DNA synthesis (ref. 6, Fig. 4). This could have been a result of unbalanced growth as they suggest; however, before that conclusion is reached, consideration should be given to a possible alternative, namely, that RNA synthesis was continuing only as long as permitted by biochemical balance (that is until each cell in turn reached

the boundary between  $G_1$  and  $S$ ). A calculation for the latter possibility, assuming RNA to increase linearly by a factor of 2 around the life cycle and DNA to double during the  $S$  phase, yields a factor of 1.21 for the increase of RNA relative to DNA for the thymidine-blocked "balanced" culture with all cells stopped at  $S$  or at the boundary between  $G_1$  and  $S$ . (The data used for the HeLa cell life cycle were from Puck and Steffan<sup>7</sup>.) This condition should be reached about 14 h after the thymidine block became effective. Growth in the presence of thymidine probably was unbalanced, but two-thirds of the observed increase in RNA can be accounted for by age redistribution. So large an effect should not be neglected when gross chemical composition of a culture is used as a criterion of balanced growth.

8	9.5	3.5	1.6
9 (bottom)	4.2	3.6	1.5

characterized by radioimmuno-electrophoresis<sup>7</sup> and the Farr technique<sup>8</sup>; a detailed account of the preparation of BSA labelled with iodine-131 (BSA\*) is given elsewhere<sup>11</sup>.

Table 1 shows the binding data of the nine sucrose gradient fractions of pooled sera using three concentrations of BSA\*. Each 0.5 ml. sucrose gradient fraction was diluted with 0.5 ml. of 20 per cent normal rabbit serum to ensure uniform ammonium sulphate precipitation. When 0.01  $\mu$ g nitrogen BSA\* was used substantial binding of BSA\* was observed in both the 7S (fractions 3 and 4) and the 19S (fractions 6-8) portions of the sucrose gradient. In contrast, little if any binding was noted in the 19S region when 1.00  $\mu$ g nitrogen BSA\* was used. To ensure that the binding activity which we observed in fractions 6-8 using 0.01  $\mu$ g nitrogen BSA\* was due to the presence of 19S antibody and not due to contaminating 7S antibody, we analysed the 19S-1, 19S-2 and 19S-3 portions of the recycled 19S 'Sephadex' peak for binding activity using five concentrations of BSA\* over a 10,000-fold range. The results are shown in Fig. 1. Positive binding of the 19S-1 and 19S-2 fractions was obtained only when from 0.001 to 0.100  $\mu$ g nitrogen BSA\* was employed (binding of 5 per cent or less was not considered a definitive result); fraction 19S-3 showed binding up to 1.00  $\mu$ g

## IMMUNOLOGY

### Sensitivity and Detection of 19S Antibody by the Farr Technique

THE detection of humoral antibody can only be adequately assessed by using techniques which are solely dependent on the primary interaction of antigen and antibody<sup>1-5</sup>. Two such primary measures of antibody detection are the Farr technique<sup>6</sup> and radioimmuno-electrophoresis<sup>7</sup>. Radioimmuno-electrophoresis is an extremely sensitive test which is dependent on the specific activity of the labelled antigen. It is, however, qualitative, whereas the Farr technique is a quantitative test to determine either the capacity of an antiserum to bind the antigen<sup>6</sup> or the amount of antibody<sup>8,9</sup> the antiserum contains. Recently, the sensitivity of the Farr technique has been questioned, especially with respect to the detection of 19S antibody<sup>10</sup>. The work reported here shows that 19S antibody can readily be detected by the Farr technique only if an appropriate concentration of antigen is used to achieve maximum sensitivity of the method.

Ten adult New Zealand White rabbits were immunized intravenously with 50 mg bovine serum albumin (BSA) either absorbed onto aluminium hydroxide or in conjunction with a heat-killed suspension of *Corynebacterium parvum* which is a powerful adjuvant<sup>11</sup>. The rabbits were bled 9 and 12 days later and the sera pooled. 20 ml. of the pooled sera was fractionated by gel filtration through 'Sephadex G-200' using a 6 x 80 cm column and 0.075 molar phosphate buffer, pH 7.0) containing 0.075 molar sodium chloride. The 19S peak was concentrated by negative pressure dialysis to 5 ml. and recycled through a 2.5 x 35 cm 'Sephadex G-200' column. The pooled sera and the ascending (19S-1) and descending portion (19S-2 and 19S-3) of the recycled 'Sephadex' 19S peak were fractionated by sucrose density gradient ultracentrifugation as previously described<sup>12</sup>. Anti-BSA antibody activity was

<sup>+</sup> Percentage binding of a 1:3 dilution (undilute with respect to neat serum).

<sup>±</sup> Percentage binding of a 1:30 dilution.

Fig. 1.

nitrogen BSA\*. Studies of binding by the sucrose gradient fractions of the 19S-1 and 19S-2 portions of the recycled 'Sephadex' peak using 0.01 µg nitrogen BSA\* revealed activity exclusively of the 19S class; 19S-3 showed binding predominantly of the 7S class. These data were supported by radioimmuno-electrophoresis of the three 19S 'Sephadex' fractions; 19S-1 and 19S-2 contained only IgM anti-BSA antibody whereas 19S-3 contained only IgG anti-BSA antibody.

We have shown here, as have others<sup>1,2,5</sup>, that 19S (IgM) antibody can be readily detected by the Farr technique. Rosenquist and Gilden<sup>13</sup>, on the other hand, were unable to detect 19S anti-BSA antibody in early, primary response chicken sera using from 1 to 10 µg BSA\*. Similarly Wei and Stavitsky<sup>10</sup> reported that the Farr technique, using 12.5 µg human serum albumin (HSA), lacked the sensitivity needed to detect 19S antibody to HSA in rabbits which could be detected by passive haemagglutination and radioimmuno-electrophoresis. In the light of the present findings it is not surprising that these authors were unable to find binding by 19S in view of the relatively large amount of antigen used. We consider that the Farr technique can be a highly sensitive test for the detection of small amounts of antibody (including IgM) provided that small concentrations of antigen, for example, 0.001–0.010 µg nitrogen BSA\*, are used. It should be emphasized that in experiments where small amounts of antibody may be present, for example, in studies of acquired immunological tolerance, it is essential to use sufficiently small amounts of antigen to ensure adequate sensitivity of the test. In view of the recent advances in the preparation of iodine-131 labelled proteins with high specific activity<sup>14</sup>, the concentrations of antigen suggested in this report should present little experimental difficulty.

### Use of Tissue Culture to restore Immunological Competence to the Neonatally Thymectomized Mouse

MILLER<sup>1</sup> has reported a lack of development of lymphoid tissue in mice after neonatal thymectomy. These mice had a low lymphocyte count in the peripheral blood, and both spleen and lymph nodes failed to develop germinal centres and only a few plasma cells were found in them. In addition, he found that allogeneic skin which was rejected in 10 or 12 days by normal mice grafted when 5 days old survived and flourished for more than 2 months in animals thymectomized at birth. On the other hand, animals

thymectomized at birth which received a syngeneic homograft of thymus at the age of 3 weeks were able to reject allogeneic skin homografts like normal intact animals.

Although mice thymectomized at or after 3 weeks of age grow normally and have a normal life span, most strains thymectomized at birth suffer from a wasting syndrome similar to that seen in graft-versus-host reactions in *F<sub>1</sub>* hybrid mice injected with parental lymphoid cells. They grow normally for a time and then show wasting, lethargy, ruffled hair, hunched posture, diarrhoea and finally die<sup>2,3</sup>. This syndrome has been shown to be caused by infection with micro-organisms in animals unable to form antibodies<sup>4</sup>; neonatally thymectomized mice reared in a pathogen-free environment gained weight normally and did not develop the wasting syndrome.

Auerbach<sup>5</sup> showed that spleens of 13 or 14 day mouse embryos grown alone in tissue culture failed to thrive, but if they were grown in combination with embryonic thymus they produced lymphoid follicles which remained for more than 5 weeks.

Neonatally thymectomized mice implanted intraperitoneally by Osaba and Miller<sup>6</sup> at 7 days of age with 'Millipore' diffusion chambers containing embryonic or neonatal thymus tissue did not develop the wasting syndrome and could reject allogeneic skin homografts. These experiments seem to suggest that a humoral factor is made by the thymus, and that this is responsible for producing immunological competence in newborn animals. The following experiments were carried out in an attempt to determine the existence of such a factor.

Two inbred strains of mice, *A2G* and *C3H*, were used. The offspring of the originals and three subsequent generations were thymectomized within 24 h of birth and reared with their mothers until weaned at about 28 days.

Three whole thymuses from the newborn mice were explanted on the sides of each 10 × 1.3 cm test tube which was then incubated at 37° C for 1 h to ensure attachment of the thymuses to the glass surface. Growth medium (1 ml.) was then added and the tubes were incubated at 37° C at 5° to the horizontal. The growth medium was medium 199 (ref. 7) containing 0.15 per cent sodium bicarbonate and 20 per cent horse serum. To this was added 100 U of penicillin, 100 µg of streptomycin and 50 U/ml. of nystatin.

At first the effect of injecting the tissue culture fluid was studied. The medium was decanted at periods between 3 and 7 days after explantation and stored at 4° C. It was then injected in 0.3 ml. and later 0.6 ml. amounts intraperitoneally on five occasions within a period of 10 days into neonatally thymectomized mice aged between 5 and 30 days. The animals tolerated the larger amount well. Similar amounts of the unused growth medium were administered intraperitoneally to neonatally thymectomized mice as a control. Between 56 and 70 days later the cells of the spleen which produced antibody were measured.

A second series of animals were grafted at the age of 28–42 days with explants of whole syngeneic thymus grown in tissue culture for 1–9 days. Under ether anaesthetic, the explants were introduced beneath the capsule of the left kidney with an 18 s.w.g. lumbar puncture needle (personal communication from E. A. Wright). The abdominal muscle and skin were then repaired with interrupted braided silk sutures. Between 42 and 56 days later, the cells of the spleen which produce antibody were measured and the graft was examined histologically.

The antibody producing cells of the spleen were measured by the method of Jerne *et al.*<sup>8</sup>. Washed sheep erythrocytes in samples of 0.2 ml. of a 50 per cent suspension were injected intraperitoneally into the mice. Four days later, the mice were killed, the spleens were removed and a suspension of spleen cells was prepared. This was mixed with fresh sheep erythrocytes and DEAE-dextran and poured in a base of molten agar on a solid agar plate. After incubation at 37° C for 3 or 4 h, complement was added for 30 min. When it was washed away, plaques of haemolysis

surrounding each spleen cell which had produced haemolysis were counted. The total number of plaques/million spleen cells in the suspension was calculated.

Fifty-one neonatally thymectomized mice were given intraperitoneal injections of tissue culture explant fluid and forty-five were given similar injections of unused growth medium as controls. Table 1 shows the average number of plaques/ $10^6$  cells in both test and control animals of different ages. Each time an experiment was performed, a normal unthymectomized mouse was used as an additional control, and each time it produced more than 100 plaques/ $10^6$  cells.

Twenty-two neonatally thymectomized mice received grafts of thymus explants. Table 2 shows the average number of plaques/ $10^6$  spleen cells in mice given grafts of different ages in tissue culture. Again, each time an experiment was performed, an unthymectomized mouse was tested and produced more than 100 plaques/ $10^6$  cells. Fig. 1 shows a section of a neonatal thymus grown in tissue culture for 4 days and then grafted beneath the renal capsule of a 33 day old neonatally thymectomized mouse. It was allowed to grow on this site for 45 days.

Neonatally thymectomized mice have a severely impaired capacity to produce cells in their spleen which will haemolyse sheep erythrocytes<sup>9</sup>. An estimation of these "plaque forming cells" is a particularly convenient method of assessing the capacity of a thymectomized mouse to form antibodies, and has been used in the present experiment to determine the effects of tissue culture explant fluid on the immune response of such animals.

The results indicate that thymuses grown in tissue culture do not secrete a humoral substance capable of restoring the antibody forming capacity of neonatally thymectomized mice. This could be caused by degeneration and death of the explants with a consequent failure to produce the substance. But thymic explants in tissue culture for periods up to 9 days were found to be viable when transplanted under the renal capsule of syngeneic thymectomized mice. Not only were they well preserved histologically but they also led to a considerable restoration of antibody forming capacity in these animals. This agrees well with Miller's observation that thymic tissue grafts restore to neonatally thymectomized mice the capacity to effect transplantation immune reactions<sup>1</sup>. It has been shown that most of the lymphoid cells in the graft were eventually derived from invading host cells<sup>10-13</sup>, but in our experiment no attempt has been made to assess the origin of the cells of the graft.

The experiments of Osaba and Miller<sup>6</sup>, where the thymic implant placed in a 'Millipore' diffusion chamber within the peritoneal cavity of young neonatally thymectomized mice restored the immune capacity of the animals, suggest

Fig. 1. Section of a neonatal thymus grown in tissue culture for 4 days and then grafted beneath the renal capsule of a 33 day old neonatally thymectomized mouse. It was allowed to grow in this site for 45 days. Stained with haematoxylin and eosin ( $\times 25$ ).

Table 1. PLAQUES IN TEST AND CONTROL ANIMALS OF DIFFERENT AGES AFTER INJECTION OF TISSUE CULTURE EXPLANT FLUID

Age during which fluid was given	No. of test animals	Average No. of plaques/ $10^6$ cells	No. of control animals	Average No. of plaques/ $10^6$ cells
5-15 days	19	15	18	14
15-20 days	15	13	11	10
15-25 days	10	10	9	9
20-30 days	7	10	7	10
Total No. of animals	51	12	45	11

Neonatally thymectomized mice were given intraperitoneal injections of tissue culture explant fluid. The controls were given injections of unused growth medium. The number of antibody producing cells was calculated. Unthymectomized mice tested at the same time showed more than 100 plaques/ $10^6$  spleen cells.

Table 2. PLAQUES IN MICE AFTER GRAFTING OF THYMUS EXPLANTS

No. of days of explant in tissue culture before grafting	No. of animals	Average No. of plaques/ $10^6$ spleen cells
1	3	75
2	2	81
3	5	70
4	4	75
5	2	80
6	1	75
7	2	80
8	1	75
9	2	70
Total No. of animals	22	75

Neonatally thymectomized mice were grafted with thymuses grown in tissue culture for 1-9 days. They were killed 42-56 days later, and good grafts were present beneath the renal capsule. The number of antibody producing cells was calculated. Unthymectomized mice tested at the same time showed more than 100 plaques/ $10^6$  spleen cells.

that a humoral mechanism may be important in the establishment of a functioning immunological system. The failure to find such a diffusible factor in tissue culture fluids of thymic explants would appear to negate this possibility. It can, however, be argued that thymic explants in tissue culture medium are surviving in a foreign environment, and that their metabolic processes cannot be equated with those of the thymus in a living animal. Nevertheless, thymic extracts have so far failed to restore antibody forming capacity in thymectomized mice, and it may well be that the interaction between thymus and immature lymphocytes takes place at a more intimate cellular level.

This investigation was supported by a grant from the MRC. We thank Dr J. F. A. P. Miller for his help.

## PATHOLOGY

### Lymphoid Cells in Hodgkin's Disease

THERE is now considerable evidence that there are in animals tumour specific antigens of a transplantation type, that the host reacts against its own tumour and that this reaction is in some cases immunological, mediated by lymphocytes and similar to the delayed hypersensitivity reaction and homograft rejection<sup>1</sup>. The situation in man

is not so clear because of the difficulty of research. We therefore decided to study the morphology and DNA synthesis of lymphocytes in Hodgkin's disease for two reasons. First, in this disease cellular immunity is depressed more than in any other human malignant disease; and second, lymphocytic and/or histiocytic proliferation is associated with localized disease and a relatively good prognosis, whereas lymphocytic depletion is associated with a poor prognosis and a generalized disease<sup>2,3</sup>.

Lymphoid cells were obtained from defibrinated blood using finely divided iron particles and methyl cellulose<sup>4</sup>. The preparations contained 98-100 per cent lymphoid cells, the phagocytic monocytes and granulocytes having been removed.

In fourteen out of eighteen untreated patients with Hodgkin's disease there was a definite increase in the number of large lymphoid cells (Fig. 1), which were approximately 20 $\mu$  in diameter, with prominent nucleoli, deeply basophilic cytoplasm, and a well developed Golgi zone, and which on electron microscopy had large numbers of ribosomes arranged in rosettes, but little endoplasmic reticulum. Similar cells are found in the efferent lymph nodes draining the sites of antigenic stimulation in experimental animals<sup>5,6</sup>. In addition there is also an increased number of medium-sized lymphocytes with basophilic cytoplasm, an increased ribosomal content and, in some, well developed endoplasmic reticulum.

DNA synthesis in the lymphoid cells was assessed by measuring, in a liquid scintillation counter, the amount of tritiated thymidine taken up by the cells after incubation for 30 min, using the technique of Cooper<sup>7</sup>. The cells were not stimulated by phytohaemagglutinin or any other agent. The results, shown in Fig. 2, are expressed as c.p.m./million cells. In fifteen of the seventeen patients studied, the DNA synthesis was greater than the upper limit of normal controls.

As expected, autoradiographs have shown that the large lymphoid cells constitute nearly all the labelled cells and smaller lymphocytes were only occasionally labelled. Kuper *et al.*<sup>8</sup> also noted increased uptake of tritiated thymidine in the mononuclear cells in three patients with Hodgkin's disease, but did not state whether these were lymphoid cells.

These changes in the lymphoid cell population may be seen in all stages of Hodgkin's disease and in the presence of normal or low haemoglobin, serum folate levels and total lymphocyte counts. In addition there is no apparent

Fig. 1. Percentage of large lymphoid cells in peripheral blood lymphocyte preparations.

Fig. 2. DNA synthesis in peripheral blood lymphoid cells.

correlation with the ability to give delayed hypersensitivity reactions to tuberculin and streptokinase.

One possible explanation for these findings is that the lymphocytes in Hodgkin's disease are involved in an "immunological" reaction against the disease, and we therefore studied the lymphoid cells in the peripheral blood of patients with a variety of infections, normal subjects after immunization and patients with rheumatoid arthritis. The results are shown in Figs. 1 and 2.

We excluded those bacterial, viral and rickettsial infections in which labelled mononuclear cells had previously been described<sup>9-11</sup>. Only some of the patients with bacterial infections had an increased number of large lymphoid cells and they were suffering from a staphylococcal pneumonia and empyema, bronchopneumonia and acute pyelonephritis. Two laboratory workers with common colds, and four volunteers, who were injected with antigens (killed poliovaccine and tetanus toxoid intramuscularly, and tuberculin and streptokinase intradermally) also showed changes in morphology and DNA synthesis of the same type as that found in Hodgkin's disease. Following immunization, more than a four-fold rise was found in the numbers of large lymphoid cells synthesizing DNA, and up to 1.1 per cent of the cells were labelled using autoradiographic techniques. This rise was followed by a subsequent return to normal levels.

Increased numbers of peripheral blood lymphoid cells synthesizing DNA have been described in patients with auto-immune diseases<sup>12</sup>, and the three patients with rheumatoid arthritis whom we studied showed morphological changes indistinguishable from those in Hodgkin's disease.

These results support the theory that the changes in the lymphocytes in Hodgkin's disease could represent an immunological reaction, but other possibilities exist. For example, it is known that malignant cells in the peripheral blood actively synthesize DNA. This is unlikely in our cases because we were unable to find any reticulum or Reed-Sternberg cells in the lymphoid cell preparations, and because it is improbable that the large lymphoid cells are the malignant cells in Hodgkin's disease.

Another possibility is that, because of disorganization of the normal lymph node architecture, increased numbers of immature lymphoid cells appear in the peripheral blood

just as, with infiltration of the bone marrow, primitive bone marrow cells appear in the blood causing a leucoerythroblastic anaemia. The patients we have studied with carcinomatous infiltration of the lymph nodes, however, have usually had normal lymphoid cell populations in the peripheral blood. We are now extending the study to include more patients with carcinoma and reticulum cell sarcoma.

Undoubtedly, the most attractive hypothesis, which leads to the greatest amount of further research, is that the changes in Hodgkin's disease represent an immunological reaction. Whether this is directed against tumour specific antigens and hence the disease, or against some undiscovered subclinical infection, remains to be proved.

We thank the Wellcome Foundation for support and Mr M. S. C. Birbeck of the Chester Beatty Research Institute, London, for the electron microscopy.

## BIOCHEMISTRY

### Pentitols and the Mechanism of Insulin Release

ALTHOUGH glucose was for a long time considered the most important physiological agent for stimulating release of the insulin from the islets of Langerhans, there have recently been reports that the five carbon polyhydric alcohol xylitol is also active in causing insulin secretion, either in whole animals<sup>1</sup> or in perfused pancreas preparations<sup>2</sup>. The substance is believed to be metabolized in mammalian tissues through the pentose phosphate pathway<sup>3</sup>. Because this pathway seems to be important in the release of insulin<sup>4,5</sup>, the effects of pentitols and pentoses on insulin secretion have been examined in greater detail, using isolated rat islets of Langerhans.

Islets of Langerhans were isolated from pancreas taken from male albino Wistar rats which had been fasted overnight. The islets were obtained free from acinar tissue using collagenase as in methods already described<sup>6,7</sup>. The separated islets were incubated at 37° C for 30 min in a bicarbonate buffered medium, containing 2.5 mmolar glucose. After the pre-incubation period, the islets were divided into groups of ten, and incubated for a further 30 min in medium containing albumin, together with either glucose, pentose or pentitol. The medium was then sampled for determination of its insulin content by immunoassay<sup>8</sup>.

The results of incubations are shown in Table 1. It can be seen that, in addition to xylitol, ribitol and ribose markedly stimulate the release of insulin. Ribitol and ribose are as effective as glucose, although xylitol is more effective; it has not previously been shown that ribitol stimulates insulin release. It has also been demonstrated

that the polyhydric alcohols arabitol, sorbitol and mannitol and the pentoses, xylose and arabinose, are without effect on insulin secretion<sup>9</sup>. None of these other polyhydric alcohols or pentoses are metabolized through the pentose phosphate pathway in mammalian tissues<sup>3</sup>. On the other hand, the three compounds ribose, ribitol and xylitol are all known to be readily metabolized through this pathway<sup>3</sup> and all promote insulin release.

Table 1. EFFECTS OF GLUCOSE, XYLITOL, RIBITOL AND RIBOSE ON INSULIN RELEASE FROM ISOLATED RAT ISLETS

Substance in medium	Concentration (mmolar)	Insulin release (mean $\pm$ S.E.M.) $\mu$ U insulin/ten islets/min
Glucose	2.5	19 $\pm$ 0.9 (40)
	20	37 $\pm$ 1.1 (40)
Xylitol	2.5	16 $\pm$ 1.6 (20)
	20	45 $\pm$ 1.6 (20)
Ribitol	2.5	18 $\pm$ 1.1 (20)
	20	38 $\pm$ 2.0 (20)
Ribose	2.5	18 $\pm$ 1.1 (20)
	20	41 $\pm$ 1.6 (20)

Numbers of observations are in parentheses.

Evidence about the mechanism of release by pentoses and hexoses has been provided from a study of the effects of adrenaline on insulin release. This is already known to inhibit the secretion of insulin caused by glucose both *in vivo*<sup>10</sup> and *in vitro*<sup>11</sup>. The effects of low concentrations of adrenaline on insulin release from isolated islets in the presence of xylitol are shown in Table 2. It can be seen that adrenaline is a potent inhibitor of insulin release caused by xylitol, as well as of release caused by glucose. This suggests that both glucose and xylitol are effective through a common adrenaline sensitive pathway.

Table 2. THE EFFECTS OF ADRENALINE (200  $\mu$ g/ML.) ON INSULIN RELEASE FROM ISOLATED RAT ISLETS IN THE PRESENCE OF GLUCOSE AND XYLITOL

Substance in medium	Insulin release (mean $\pm$ S.E.M.) $\mu$ U insulin/ten islets/min	
	Without adrenaline	With adrenaline
Glucose (20 mmolar)	40 $\pm$ 1.8 (15)	23 $\pm$ 1.3 (15)
Xylitol (20 mmolar)	46 $\pm$ 1.8 (15)	22 $\pm$ 1.5 (15)

Numbers of observations are in parentheses.

We do not know the complete biochemical sequence of events by which hexose sugars release insulin, although it seems likely that in order to stimulate release, hexoses have first to be metabolized to pentose phosphates.

Further evidence for this has been obtained by studying the effects of 2-deoxy-glucose on insulin secretion in this system. Equimolar concentrations of this substance inhibit the effects of glucose in stimulating insulin release but not those of xylitol. Because 2-deoxy-glucose is known to inhibit phosphohexoseisomerase<sup>12</sup> and glucose-6-phosphate dehydrogenase<sup>13</sup>, this indicates that xylitol is not being metabolized to glucose-6-phosphate, but rather that it is converted to another pentose derivative more directly concerned with insulin release.

The results shown in this communication strongly suggest a direct involvement of the pentose phosphate pathway in insulin release caused by sugars. On this basis, the mechanism of insulin release due to glucose may be as follows: glucose is first metabolized to a pentose by way of the pentose phosphate pathway, and some further metabolite of this affects the release of insulin. There is evidence that the later stages of the release mechanism may involve the synthesis and breakdown of cyclic 3' 5'-AMP (refs. 14 and 15). It may be that a pentose, or some derivative of a pentose, regulates the concentration of this substance intracellularly.

We thank the Medical Research Council for a personal grant (to K. W. T.), and the British Diabetic Association

for help in supporting these investigations. We also thank Professor J. Anderson for his continued help and interest.

### Loss of Neural Inductive Capacity of the Chick Primary Organizer by Treatment with Histone and its Restoration by Follicle-stimulating Hormone

THERE is some evidence that histones inhibit synthesis of DNA-dependent RNAs and thereby regulate genetic activity<sup>1-3</sup>. If this is so they should influence embryonic development by interfering with the differential expression of genetic activity. The effects of calf thymus histone fractions on the development of the chick embryos seem to depend on the stage chosen for treatment while those of poly-L-lysine do not<sup>4,5</sup>. Such effects are presumably caused by histones complexing with cytoplasmic molecules such as those concerned in embryonic inductions which appear in a sequential order during development<sup>6</sup>.

The primary organizer of a chick primitive-streak embryo induces formation of secondary neural tissue when it is placed between the epiblast and hypoblast of a host embryo<sup>7</sup>. This phenomenon obviously consists of a derepression of specific genes, the derepression being produced by the inductor molecules derived from the organizer graft. We have therefore chosen this process of neural induction as an experimental system and have studied the effects of the F1-histone fraction to elicit information on the possible interaction between the inductor molecules and the histones.

The organizer pieces (only the Hensen's nodes were actually used) were excised from primitive-streak embryos and placed in histone solution (2.5 mg/ml.) for 3 h, washed for 1 h in Pannett-Compton (PC) saline and transplanted into host primitive-streak embryos. Control grafts were placed in the same saline for 4 h and then transplanted.

The capacity of the grafts to form neural induction has been expressed as the "induction index" which reflects both the frequency and quality of neural inductions (see note in Table 1).

It will be seen from Table 1 that after a 3 h treatment with histone, grafts failed to produce inductions (Fig. 1). Reduction of histone treatment to 2 h resulted in a slight retention of the inductive capacity (Fig. 2). This may indicate that the loss of the inductive capacity is due to the histone complexing with the inducing molecules found in the organizer graft.

Table 1. INDUCTIVE CAPACITY OF HENSEN'S NODE GRAFTS AFTER HISTONE AND FSH TREATMENTS

Experiment	Histone treatment (h)	FSH treatment (h)	No. of grafts	No.	Inductions	A	B	C	D	Induction index
1 C	—	—	7	6	2	1	8	—	—	2.44
E	3	—	16	—	—	—	—	—	—	0
2 C	3	—	17	—	—	—	—	—	—	0
E 1	3	1	5	1	—	1	—	—	—	0.6
E 2	3	2	13	6	3	—	2	1	—	1.31
3 C	2	—	17	6	1	1	3	1	—	0.82
E 1	2	1	8	3	2	—	1	—	—	1.25
E 2	2	2	6	6	3	1	2	—	—	2.8
E 3	2	3	13	11	1	4	5	1	—	2.1

The induction index is arrived at as follows: The inductions produced are classified as A, B, C, D, based on their quality and scored 4, 3, 2, 1 respectively. The total points are divided by the number of grafts (including those which failed to induce neural tissue). The induction index therefore takes into account the frequency as well as the quality of inductions.

Histones are said to be highly toxic. But organizer grafts treated with histone seemed to be in a healthy state despite the use of large amounts of histones (Fig. 3). They did not, however, differentiate into neural tubes, while the control grafts did (Fig. 4).

The effects of poly-L-lysine and lysozyme were studied in similar experiments in order to see if the effects of histone were specific. The induction index of pieces of Hensen's node was 2.8 after 3 h of treatment with poly-L-lysine. Even a long treatment, up to 24 h, had no effect. The grafts, however, showed an abnormal cytological picture with most of the cells undergoing cytolysis. It is

Fig. 1. Graft treated with histone 3 h illustrates the loss of neural inductive capacity. GR, graft.

Fig. 2. Graft treated with histone 2 h showing induction of a lump of neural tissue (INT).

Fig. 3. Graft treated with histone 3 h to show the state of graft cells (GR).

possible that the inductive capacity of the grafts treated with polylysine may not have been their primary effect but may be caused by influences released from the cytolyzing cells. This point was checked using post-nodal pieces of primitive-streak which normally possess little inductive power<sup>9</sup>. In the controls of this series *PN-1* pieces (those pieces of primitive-streak from 0.8 mm behind the Hensen's node) had an induction index of 0.25. Treatment of these pieces with poly-L-lysine did not cause any significant increase in the induction index (see Table 2). Incidentally, this fact tallies with our earlier observation that the morphological effects exerted by histones on chick embryos *in vitro* could not be produced by poly-L-lysine<sup>4,5</sup>. Neither did lysozyme seem to have any inhibitory effect on the inductive capacity of the Hensen's node. The histone effects therefore appear to be specific.

It may be of some interest that we have been able to restore, by using follicle-stimulating hormone (FSH), the inductive capacity which had been lost by a previous treatment with histones (Figs. 5 and 6).

The grafts were treated with histone solution as described earlier and some of them were then transferred to a solution of FSH (NIH-FSH-S2) for 1, 2 or 3 h, washed for 0.5 h and grafted into host embryos as usual. The controls were left in PC saline until grafting. Various combinations of histone and FSH treatments were used. All procedures of treatment and washing were carried out at 37° C. The results (Table 1) show that increase of FSH treatment increased the capacity of the grafts to induce neuralizations. In both sets of experiments (3 h and 2 h treatment with histone), the increase in induction index was proportional to the duration of FSH treatment.

It would be necessary at this stage to say why FSH was chosen to restore the lost inductive capacity of the Hensen's node grafts. Experiments by us have so far shown that FSH has the capacity to support and induce morphogenesis<sup>8-13</sup>.

Table 2. EFFECTS OF POLY-L-LYSINE AND LYSOZYME ON THE INDUCTIVE CAPACITY OF *HN* AND *PN-1* GRAFTS

Inhibitor	Graft	Dura- tion of treatment	No. of grafts	Induc- tions	A	B	C	D	Induc- tion index
Poly-L-lysine (2.5 mg/ml.)	<i>HN</i>	3 h	15	15	4	6	3	2	2.8
		24 h	4	3	1	2	—	—	2.5
	<i>PN-1</i>	3 h	7	3	—	—	—	3	0.42
No inhibitor (control)	<i>PN-1</i>		8	2	—	—	—	2	0.25
Lysozyme (2.5 mg/ml.)	<i>HN</i>	3 h	18	18	13	4	—	1	3.6

*HN*, Hensen's node; *PN-1*, primitive-streak pieces 0.8 mm behind *HN*.

From the present experiments, it seems likely that histones complex with the inductor molecules to be found in the inducing system and cause a loss of the neural inductive capacity and that as FSH is put into the system this capacity increases. This could be caused by a direct inductive effect exerted by the FSH molecules or to a release of the natural inductor by a shift in the equilibrium leading to a breakdown of the inductor-histone complex after increase of the concentration of FSH.

These observations seem to show clearly the morphogenetic effects of FSH and also suggest that the FSH molecules may be similar to the inductive molecules. This is a very interesting possibility because ovary is the target organ of FSH and it is plausible that FSH could be localized in the developing ovum and take part in subsequent morphogenesis. Incidentally, these experiments can also be interpreted as suggesting that in primary embryonic induction the inducing stimulus acts in a genotropic way, that is, by impinging directly on the DNA and derepressing the genes.

We thank Professor Sir Alexander Haddow for his interest. This work was supported by a grant from the Damon Runyon Memorial Fund for Cancer Research, and also by grants from the MRC, the British Empire Cancer Campaign for Research and the US Public Health Service.

## Reaction of Ethyl Isocyanide with Haemocyanin

MANY compounds have been tested for their ability to react with the oxygen-binding site of haemocyanin and it has been found that thiourea<sup>1</sup> and thiocyanate<sup>2</sup> cause the expulsion of oxygen from *Helix pomatia* haemocyanin with a consequent decrease in the absorption of the copper bands at 346 and 570 m $\mu$ . This effect was almost completely reversed by dialysis or by treatment with an anion exchange resin. A report on the exchange reaction of ethyl isocyanide with oxygen in oxyhaemoglobin<sup>3</sup> encouraged us to investigate the effect of this compound on haemocyanin. Ethyl isocyanide does not remove copper from haemocyanin, but it does cause a decrease in the copper bands, which presumably indicates the expulsion of oxygen.

Haemocyanin was obtained from the haemolymph of the whelk, *Murex trunculus*, either by the method of Bannister *et al.*<sup>4</sup>, or by passing the haemolymph through a column (80  $\times$  2.4 cm) of 'Sephadex G-200' equilibrated with 0.05 molar *tris*-hydrochloric acid, pH 7.0, containing 0.1 molar potassium chloride. Ethyl isocyanide was synthesized by the method of Jackson and McKusick<sup>5</sup>. Copper was estimated by the method of Peterson and Bollier<sup>6</sup>, and protein was estimated from the absorbance at 280 m $\mu$  in 0.1 molar borate buffer, pH 9.2 at which pH the error caused by light scattering is minimal<sup>7</sup>.

The addition of ethyl isocyanide in concentrations from 0.5 to 50 mmolar to the haemocyanin caused a very rapid decrease in the copper bands at 346 and 570 m $\mu$ . The reaction was almost complete in less than 1 min at room temperature, and thereafter there was a slow drop in absorbance during a period of hours. Fig. 1 shows the relationship between concentration of ethyl isocyanide and absorbance at 346 m $\mu$  after 3 min (that is when the reaction is at least 95 per cent complete). The slow decrease in absorbance over longer periods may be partly caused by the fact that ethyl isocyanide is gradually hydrolysed in aqueous solution with the production of cyanide, which removes the copper from haemocyanin.

That ethyl isocyanide does not remove the copper atoms from haemocyanin is illustrated by the following experiment. To 3 ml. of haemocyanin (34.5 mg) in 0.1 molar phosphate buffer, pH 7.5, was added 0.05 ml. ethyl isocyanide (0.7 mmoles). The absorbance at 570 m $\mu$  was noted continuously for 10 min, during which time it dropped by 44 per cent. The solution was then passed through a column (40  $\times$  2.4 cm) of 'Sephadex G-25' equilibrated with 0.1 molar *tris*-hydrochloric acid, pH 8.3. The protein-containing fractions of the eluate were

pooled and analysed for copper in duplicate. The original haemocyanin solution was analysed for copper at the same time. Aliquots of the column effluent and of the original haemocyanin were diluted in 0.1 molar borate buffer, pH 9.2, and their absorption spectra were recorded in a Beckman 'DB' spectrophotometer. The copper content of the original haemocyanin was 0.240 per cent, and that of the haemocyanin treated with ethyl isocyanide was 0.250 per cent. From the absorption spectra, the ratios  $E_{346m\mu}/E_{280m\mu}$  and  $E_{570m\mu}/E_{280m\mu}$  were calculated. The values of these ratios were, for haemocyanin, 0.282 and 0.022; and for ethyl isocyanide-treated haemocyanin, 0.263 and 0.019, respectively. It was possible to regenerate the copper bands simply by bubbling oxygen through the mixture of ethyl isocyanide and haemocyanin. Ethyl isocyanide was added to haemocyanin in 0.1 molar phosphate buffer at pH 7.5. After 5 min the absorbance at 346 m $\mu$  had decreased to 45 per cent of its original value. Pure oxygen was then bubbled through the mixture for 10 min. After 5 min the absorbance had risen to 76 per cent, and after 10 min to 80 per cent of its original value.

The exchange reaction of ethyl isocyanide with oxygen in oxyhaemocyanin should prove useful in studies of the mode of binding of oxygen by haemocyanin. Ethyl isocyanide displaces the oxygen more effectively than thiourea and thiocyanate, and the reaction is easily reversible. Rombauts and Lontie<sup>1,2</sup> found that at the greatest concentrations of thiourea and thiocyanate they used, only about 10 per cent and 23 per cent respectively of the original absorbance of the copper bands remained. We have found that in optimal conditions (0.5 mg/ml. of haemocyanin in 0.1 molar borate buffer, pH 9.2; molar ratio of ethyl isocyanide to copper, 4,000) the absorbance of haemocyanin at 346 m $\mu$  can be reduced to less than 1 per cent its original value by treatment with ethyl isocyanide.

Fig. 1. Relationship between final concentration of ethyl isocyanide and absorbance of *Murex trunculus* haemocyanin at 346 m $\mu$  after 3 min. To 2.5 ml. of haemocyanin in 0.1 molar borate buffer, pH 9.2 (protein concentration, 1 mg/ml.), was added ethyl isocyanide as an emulsion in the same buffer, to the final concentration indicated. The absorbance at 346 m $\mu$  was noted continuously in a 1 cm cell. The emulsion of ethyl isocyanide also absorbed at 346 m $\mu$ , and so the same amount of ethyl isocyanide was added to 2.5 ml. of borate buffer in the reference cuvette.

## Uptake of Selenite labelled with Selenium-75 by Human Leucocytes *in vitro*

PREVIOUS work (reviewed in ref. 1) has shown that after the injection of selenite labelled with selenium-75 ( $^{75}\text{SeO}_3^{--}$ ) into animals radioactivity is incorporated into the proteins of various tissues. Recent studies in our laboratory<sup>2</sup> have demonstrated that in humans selenite is rapidly taken up by the liver, kidneys and by malignant tumours. Analyses of both normal and tumour tissues have indicated that the selenium is bound to tissue protein by a covalent linkage. We have investigated the mechanism by which inorganic selenium is taken up by human cells.

Plasma rich in leucocytes was obtained from normal human venous blood by the method of Moorhead *et al.*<sup>3</sup> using phytohaemagglutinin. Sterility was maintained throughout the procedure. To 4 ml. of this plasma was added 8 ml. of tissue culture medium, TC-199 (Difco)<sup>4</sup>, and 1 ml. of 0.9 per cent sodium chloride con-

Fig. 1. The effect of puromycin on the incorporation of labelled leucine (left) and on the uptake of labelled selenite (right) by human leucocytes *in vitro*. Puromycin (3.6  $\mu\text{g}/\text{ml}$ ) was added to the cell suspensions 10 min before addition of the radioactive tracers.

taining either 1  $\mu\text{c}$ . of labelled sodium selenite (0.03  $\mu\text{g}$  of selenium) or 5  $\mu\text{c}$ . of carbon-14 uniformly labelled L-leucine (0.02  $\mu\text{moles}$ ). Within 0.5 min of the addition of radioactivity two samples of 2 ml. were removed and the cells were separated by centrifugation. Four additional 2 ml. samples were transferred to sterile siliconized tubes, stoppered with cotton-wool. Tubes were left undisturbed in an incubator at 37° C for periods from 1 to 24 h. After incubation leucocytes were separated by centrifugation and washed twice with 3 ml. of 0.9 per cent sodium chloride. The washed cells were lysed in 0.1 molar sodium hydroxide for assay of radioactivity and determination of protein concentration.

The time course of incorporation of labelled leucine and selenium and the effect of puromycin on each are shown in Fig. 1. Puromycin (3.6  $\mu\text{g}/\text{ml}$ ) markedly inhibited the incorporation of labelled leucine, but at the same concentration had virtually no effect on the uptake of selenium. These results indicate that the incorporation of selenium is not dependent on protein synthesis.

Table 1. EFFECT OF INHIBITORS ON LABELLED SELENITE INCORPORATION BY LEUCOCYTES

Inhibitor	Concentration (mmolar)	Duration of incubation		
		Initial (0.5 min)	1 h	4 h
None	—	17,028	23,025	43,302
None	—	17,912	25,324	42,064
NaF	10.0	38,877	20,562	13,701
NaF	0.2	31,397	28,010	34,145
Iodoacetamide	10.0	468	150	195
Iodoacetamide	0.2	5,442	4,164	9,737
KCN	1.0	3,906	—	2,828
PCMB	0.5	1,158	5,261	8,842
PCMB	0.01	6,130	11,580	18,522

Inhibitors were added to the cell suspension before the addition of labelled selenite.

The effects of other inhibitors upon the uptake of selenite by leucocytes are shown in Table 1. The results suggest that two processes are involved: an almost immediate binding and a more gradual incorporation continuing for several hours. The rapidity of the initial binding indicates that enzymes are not involved. From the inhibition by iodoacetamide and *p*-chloromercuribenzoate (PCMB) sulphhydryl groups seem to be involved. The reaction may be an exchange of  $\text{SeO}_3^{2-}$  for  $-\text{SH}$  or an addition of  $\text{SeO}_3^{2-}$  to  $\text{RSH}$  yielding  $\text{RS}-\text{SeH}$  (ref. 5). The inhibition by cyanide of initial binding of selenium may also be explained by

postulating an interaction with sulphhydryl groups because cyanide reacts with cysteine residues of protein<sup>6</sup>. In a separate experiment (not included in Table 1), addition of PCMB (0.5 mmolar) to the medium after 4 h of incubation resulted in an immediate discharge of 33 per cent of the radioactive selenium already incorporated into the leucocytes.

Enhancement of the initial binding of selenium by fluoride is not readily explained. In any case more than half of the selenium bound initially was lost from the cells during continued incubation in 10 mmolar sodium fluoride (Table 1).

The second process, the slower accumulation of selenium, is clearly dependent on metabolic activity because cyanide, fluoride and iodoacetamide inhibit the process. The effect of the latter two inhibitors suggests that normal glycolysis is essential. The nature of the reactions by which selenite is incorporated into cells is unknown, but presumably a series of reduction reactions is involved<sup>5</sup>. McConnell and Roth<sup>7</sup> in their studies of the incorporation

of selenite into rat liver ribosomes *in vitro* observed that the addition of cell sap and ATP stimulated, while cyanide inhibited, uptake. Their findings, together with ours reported here, support the idea that an energy dependent process is involved in the uptake of selenite.

In addition, these results indicate that the incorporation of selenite by intact leucocytes is a complex phenomenon consisting of at least two processes which differ both in respect to rate and in susceptibility toward inhibition.

### Molecular Weight Isoenzymes of Arginine Kinase in the Mollusca and their Association with Muscle Function

CREATINE kinase from various species has always been found to have a molecular weight of about 80,000 (ref. 1) and to be composed of two subunits<sup>2-4</sup>. The subunits are of two types, one forming the enzyme (*BB*) found in brain and the other forming the enzyme (*MM*) found in the white fibres of skeletal muscle. A third, hybrid enzyme composed of one each of the two subunits (*BM*) is found in heart muscle and the red fibres of skeletal muscle<sup>3</sup>. Thus,

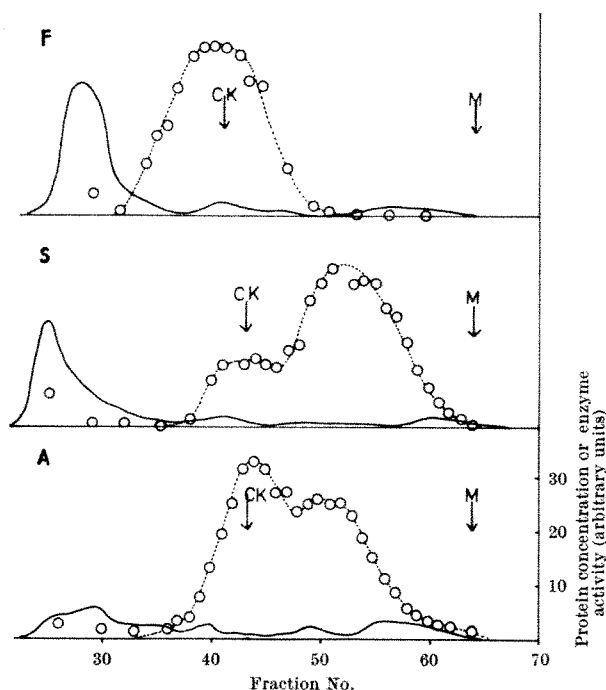

Fig. 1. 'Sephadex G-100' column elution patterns of muscle extracts of *Cardium edule*. F, Foot muscle; S, siphon muscle; A, adductor muscle. —, Protein concentration measured at 253 m $\mu$ ; ○---○, arginine kinase activity. The relative elution positions of proteins of known molecular weight are shown in the diagram; CK, rabbit creatine kinase; M, horse myoglobin.

in vertebrates, a particular enzyme type appears to be associated with the function of a particular organ or cell type.
